A Post-Pandemic New Normal for Interest Rates in Emerging Bond Markets? Evidence from Chile

Jens H. E. Christensen

Damian Romero

Abstract

Before the COVID-19 pandemic, researchers intensely debated the extent of the decline in the so-called equilibrium or natural rate of interest. Given the recent sharp increase in interest rates, we revisit this question in an emerging bond market context and offer a Chilean perspective using a dynamic term structure finance model estimated directly on the prices of individual Chilean inflation-indexed bonds with adjustments for bond-specific liquidity risk and real term premia. Beyond documenting the existence of large and time-varying liquidity risk premia in the bond prices, we estimate that the equilibrium real rate in Chile fell about 2 and a half percentage points in the 2003-2022 period and has remained low since then with model projections only suggesting a gradual reversal in coming years. Instead, recent increases in real interest rates in Chile are driven by spikes in the liquidity and term premia of inflation-indexed bond prices.

1 Introduction

Before the COVID-19 pandemic, the general level of interest rates in many developed countries had gradually declined over the previous several decades. In the 1980s and 1990s, falling inflation expectations played a key role in this decline. But in the 2000s and 2010s, actual inflation as well as survey-based measures of longer-run inflation expectations were relatively stable in many countries, including in many emerging market economies. Therefore, researchers argued that the decline in interest rates in the later decades reflected a variety of longer-run real-side factors instead of nominal ones. These real factors—such as slower productivity growth and an aging population—affect global saving and investment and can push down nominal and real yield curves by lowering the steady-state level of the safe short-term real interest rate.¹ This steady-state real rate is often called the equilibrium or natural or neutral rate of interest and is commonly defined as the short-term real rate of return that would prevail in the absence of transitory disturbances. However, some dismissed the evidence for a new lower equilibrium real rate. They downplayed the role of persistent real-side factors and argued that yields had been held down by temporary factors such as the headwinds from credit deleveraging in the aftermath of the Global Financial Crisis of 2008-2009.² However, the surge in inflation and interest rates that followed the post-pandemic economic reopening, which was severely exacerbated by Russia’s war on Ukraine launched in February 2022, has underscored the need to better understand how steady state real rates have responded to these extraordinary economic shocks. While most of the existing debate has focused on estimates drawn from *advanced* economies, we provide an *emerging market* perspective on any post-pandemic new normal for interest rates by focusing on Chile, a representative emerging market economy. Moreover, we follow Christensen and Rudebusch (2019, henceforth CR) and use financial models of inflation-indexed bond prices for our analysis.

The issue of whether there have been persistent shifts in the equilibrium real rate is of general importance. For investors, the steady-state level of the real short rate serves as an anchor for projections of the future discount rates used in valuing assets (e.g., Clarida 2014). For policymakers and researchers, the equilibrium or natural rate of interest is a policy lodestar that provides a neutral benchmark to calibrate the stance of monetary policy: Monetary policy is expansionary if the short-term real interest rate lies below the natural rate and contractionary if it lies above. A good estimate of the equilibrium real rate is also necessary to operationalize popular monetary policy rules such as the Taylor rule.³ More

²For example, see Kiley (2015), Lo and Rogoff (2015), and Taylor and Wieland (2016).

³For a recent discussion of the connection between the natural rate of interest and monetary policy in Chile, see, e.g., Box II.2 in the December 2022 Monetary Policy Report of the Central Bank of Chile. For research on the role of the natural rate in monetary policy, see Rudebusch (2001), Orphanides and Williams (2002),

recently, the post-pandemic spike in interest rates globally has given rise to intense policy debates about whether interest rates will hold steady at the new higher levels or revert back towards their pre-pandemic lows.⁴

Against this backdrop of unsettled questions surrounding the persistent decline in interest rates in the decades before the pandemic and the recent signs of a potential reversal, Chilean yield data is unique in that the Chilean government was one of the first to issue inflation-indexed bonds as early as the mid-1960s. Hence, there exists a very long-established market for these bonds. However, despite being a pioneering issuer of inflation-linked bonds, the market environment for these bonds were complicated by the massive increase in government spending during the 1970s, the consequent high inflation, and the related subsequent collapse of the banking system; see Caputo and Saravia (2018). As a consequence, we focus our analysis on the more recent period during which the Central Bank of Chile has been implementing a fully-fledged inflation-targeting regime formally adopted in 2000. Moreover, because limited data is available for the early years of trading, we start our sample in 2003 similar to De Pooter et al. (2014).

The inflation-indexed securities we consider have coupon and principal payments indexed to the Chilean Consumer Price Index (CPI) and provide compensation to investors for the erosion of purchasing power due to price inflation.⁵ Therefore, their bond prices can be expressed directly in terms of real yields. We assume that the longer-term expectations embedded in the bond prices reflect financial market participants' views about the steady state of the Chilean economy, including its natural rate of interest. This long sample is sufficient to allow us to provide a full 20-year perspective on the components that have pushed Chilean real yields lower in previous decades and given rise to any potential recent reversal. Besides its length, a Chilean study offers additional advantages. First, Chile has fairly liquid markets for inflation-indexed government debt. Second, with maturities of up to 30 years, the inflation-indexed bond market contains significant forward-looking information and hence is likely to provide clear evidence for the questions at hand. Third, by relying on inflation-indexed bonds, we avoid any issues related to the zero lower bound that applies to the Chilean overnight rate and other nominal interest rates during the pandemic period. Furthermore, as the underlying factors affecting long-term interest rates are likely global in nature—such as worldwide demographic shifts, changes in productivity trends, or persistent adjustments to global supply chains in the post-pandemic world—the Chilean government bond market may well be as informative as any other emerging sovereign bond market. Thus, we think of the data as being representative for emerging bond markets more broadly. Finally, the Chilean government holds an A+ credit rating or higher with a stable outlook from all

Eggertsson et al. (2016), and Hamilton et al. (2016), among many others.

⁴See, for example, Blanchard (2023) and Summers (2023).

⁵The CPI is also the price index targeted by the Central Bank of Chile for monetary policy purposes.

major rating agencies. Hence, there is a minimum of credit risk to account for in our Chilean bond price data, unlike what may be the case for other major Latin American countries such as Argentina and Brazil.

Despite all these advantages, using inflation-indexed bonds for measuring the steady-state short-term real interest rate has its own empirical challenges. One problem is that inflation-indexed bond prices include a real term premium. Given the generally upward slope of the Chilean inflation-indexed bond yield curve, the real term premium is presumably usually positive. However, little is known with certainty about its size or variability. In addition, despite the fairly large notional amount of outstanding inflation-indexed bonds, these securities inherently face appreciable liquidity risk for structural reasons as argued by Cardozo and Christensen (2024). Since they provide a natural hedge against inflation risk, they are likely to be much less traded than nominal bonds. Also, because this hedge argument only applies to domestic investors whose consumption expenditures track the local CPI, foreigners will not benefit from holding these securities. As a consequence, the trading of inflation-indexed bonds ends up being concentrated among patient domestic buy-and-hold investors like pension funds and insurance companies. Presumably, investors require a premium for bearing the liquidity risk associated with holding inflation-indexed bonds, but the extent and time variation of this liquidity premium deserve further examination.⁶

To estimate the natural rate of interest in the presence of liquidity and real term premia, we use an arbitrage-free dynamic term structure model of real yields augmented with a liquidity risk factor. The identification of the liquidity risk factor comes from its unique loading for each individual security as in Andreasen et al. (2021, henceforth ACR). Our analysis uses prices of individual bonds rather than the more usual input of yields from fitted synthetic curves. The underlying mechanism assumes that, over time, an increasing proportion of the outstanding inventory is locked up in buy-and-hold portfolios. Given forward-looking investor behavior, this lockup effect means that a particular bond’s sensitivity to the marketwide liquidity factor will vary depending on how seasoned and how close to maturity the bond is. In a careful study of nominal U.S. Treasuries, Fontaine and Garcia (2012) find a pervasive liquidity factor that affects all bond prices, with loadings that vary with the maturity and age of each bond. By observing a cross section of bond prices over time—each with a different time since issuance and time to maturity—we can identify the overall liquidity factor and each bond’s loading on that factor. This technique is particularly useful for analyzing inflation-indexed debt when only a limited sample of bonds may be available, as in the early years of our sample.⁷

⁶A large literature has emphasized liquidity risk as an important component in the pricing of U.S. Treasury inflation-protected securities (TIPS). See, for example, Sack and Elsassser (2004), Campbell et al. (2009), Dudley et al. (2009), Gürkaynak et al. (2010), Fleckenstein et al. (2014), Driessen, et al. (2016), and Pflueger and Viceira (2016).

⁷Finlay and Wende (2012) examine prices from a limited number of Australian inflation-indexed bonds but do not account for liquidity premia.

Figure 1: **Long-Term Nominal and Real Yields and an Estimate of r^***

Ten-year nominal and real yields and our preferred AFNS-L model estimate of the equilibrium real short rate, r_t^* , i.e., the 5- to 10-year risk-neutral real rate.

The theoretical arbitrage-free formulation of the model also provides identification of a time-varying real term premium in the pricing of inflation-indexed bonds. Identifying the liquidity premium and real term premium allows us to estimate the underlying frictionless real rate term structure and the natural rate of interest, which we measure as the average expected real short rate over a five-year period starting five years ahead, as in CR.⁸ Our preferred estimate of the natural rate of interest, r_t^* , is shown in Figure 1 along with ten-year nominal and real Chilean government bond yields. Both nominal and real long-term yields trended down together until 2020 followed by a joint sharp reversal, and this concurrence suggests little net change in inflation expectations or the inflation risk premium. In contrast, the estimated equilibrium real rate fell from just below 0.5 percent to below -2 percent during the 2003-2022 period and has remained low since then. Accordingly, our results show that the reduction in the natural rate of interest can account for about half of the 4-percentage-point decline in longer-term Chilean yields during the 2003-2020 period. Crucially, our results suggest that the recent large increases in real interest rates in Chile are driven by spikes in the liquidity and term premia of inflation-indexed bond prices, leaving the natural rate little

⁸In many macro models, the natural rate of interest is associated with the equilibrium real rate that would exist in a world without frictions. From that perspective, our approach attempts to get readings on the underlying frictionless real rates through adjustments for the liquidity and term premium imperfections that distort observed real yields. Moreover, our focus on the 5-to-10-year horizon aims to capture investors' real rate expectations in the medium term after current transitory shocks have dissipated and the economy and real rates can be expected to have returned to their steady state levels.

affected despite the yield increases. Furthermore, model projections suggest only a gradual reversal in coming years.

Our analysis also documents the existence of large and time-varying liquidity risk premia in the Chilean inflation-indexed bond prices, as conjectured by the arguments in Cardozo and Christensen (2024). Regression analysis with a large number of control variables shows that the average liquidity premium series is significantly positively correlated with the share of the market held by buy-and-hold investors as proxied through the holdings of pension funds, while it is significantly negatively correlated with the size of the indexed bond market measured as a share of nominal GDP. Hence, market concentration among domestic patient buy-and-hold investors and market size are two key determinants of investors' perceptions about the liquidity risk in this market. We take these results to imply that there are material frictions to the trading of these securities consistent with the general arguments provided in Cardozo and Christensen (2024). Moreover, they underscore the importance of the liquidity adjustment for our results.

The remainder of the paper is organized as follows. Section 2 describes how our study relates to the existing literature. Section 3 contains a description of the Chilean inflation-indexed bond data, while Section 4 details the no-arbitrage term structure models we use and presents the empirical results. Section 5 validates the estimated real bond-specific liquidity premia and examines their determinants, while Section 6 analyzes our market-based estimate of the natural rate and compares it with other measures of r_t^* . Finally, Section 7 concludes.

2 Related Literature

The analysis in this paper relates to several important strands of literature. Most directly, it speaks to the burgeoning literature on measurement of the natural rate of interest. We note that market- or finance-based estimates of r_t^* for advanced economies are reported in CR for the U.S., in Christensen et al. (2023) for Canada, in Christensen and Mouabbi (2024) for the euro area, and in Christensen and Spiegel (2024) for Japan. For emerging economies, Beauregard et al. (2024) report such an r_t^* estimate for Mexico, but it is not the focus of the analysis in that paper. Hence, our paper is the first to provide a market-based estimate of r_t^* for an emerging economy based on a comprehensive analysis solely dedicated to this purpose.

Second, our estimates of the real yield curve that would prevail without trading frictions have implications for asset pricing analysis on the true slope of the real yield curve. This issue has been explored for U.S. TIPS yields by ACR and for U.K. index-linked gilt yields by Joyce et al. (2012), but, to the best of our knowledge, no papers have examined this question in the context of emerging market real yields.

Furthermore, our results relate to research on financial market liquidity premia. For

advanced economies, we note that ACR and D’Amico et al. (2018) are among the papers performing regression analysis using their estimated liquidity risk premia of U.S. TIPS as dependent variable. Although our results regarding the estimated inflation-indexed bond liquidity risk premia are qualitatively similar to estimates reported by Beauregard et al. (2024) for Mexican udibonos and by Cardozo and Christensen (2024) for Colombian bonos tesoro UVR, we note that, to the best of our knowledge, our study is the first to perform a comprehensive regression analysis of the factors driving the liquidity risk premia of bond prices in a representative emerging inflation-indexed bond market.

Importantly, we also contribute to the empirical literature extracting macroeconomic information from asset prices. For example, the yield curve has been extensively used to measure market expectations about future growth and the probability of recessions (Estrella and Hardouvelis, 1991; Estrella and Mishkin, 1998), as well as to extract market-based measures of inflation expectations (Beauregard et al. 2024; Christensen and Spiegel, 2024). moreover, the correlation between credit spreads and equity returns has been used to extract measures of “good” and “bad” inflation, i.e., positively or negatively correlated with economic growth (Cieslak and Pflueger, 2023; Bonelli et al. 2024). Our contribution to this literature is to show that liquidity premia is an important feature of real yields that can have significant consequences for assessments of the stance of monetary policy.

Finally, our paper contributes to the rapidly growing literature about the economic consequences of the COVID-19 pandemic. Here, our contribution is to focus on the question of where monetary policy and long-term interest rates are likely to settle once inflation has returned to the target set by central banks where we offer an emerging market perspective on that important policy question.

3 The Chilean Inflation-Indexed Bond Data

The Chilean government issued its first inflation-indexed bonds back in the 1960s (see Shiller 2003). These bonds are known as bonos tesoreria UF, or BTUs for short, and their cash flow is measured in a unit known as the “Unidad de Fomento.” At the end of our sample on July 31, 2023, the net outstanding inflation-adjusted or uplifted amount of BTUs was 32,660 billion Chilean pesos, which accounted for 48.8 percent of all marketable Chilean government securities, and their average maturity was 9.58 years.⁹ The total number of outstanding inflation-indexed bonds over time in our sample is shown as a solid gray line in Figure 2(a). At the end of our sample period—which runs from August 2003 to July 2023—24 bonds were outstanding. However, as noted by Gürkaynak et al. (2010) and ACR, prices of inflation-indexed bonds near their maturity tend to be somewhat erratic because of the indexation lag

⁹The data is from Bloomberg and Riskamerica (www.riskamerica.com).

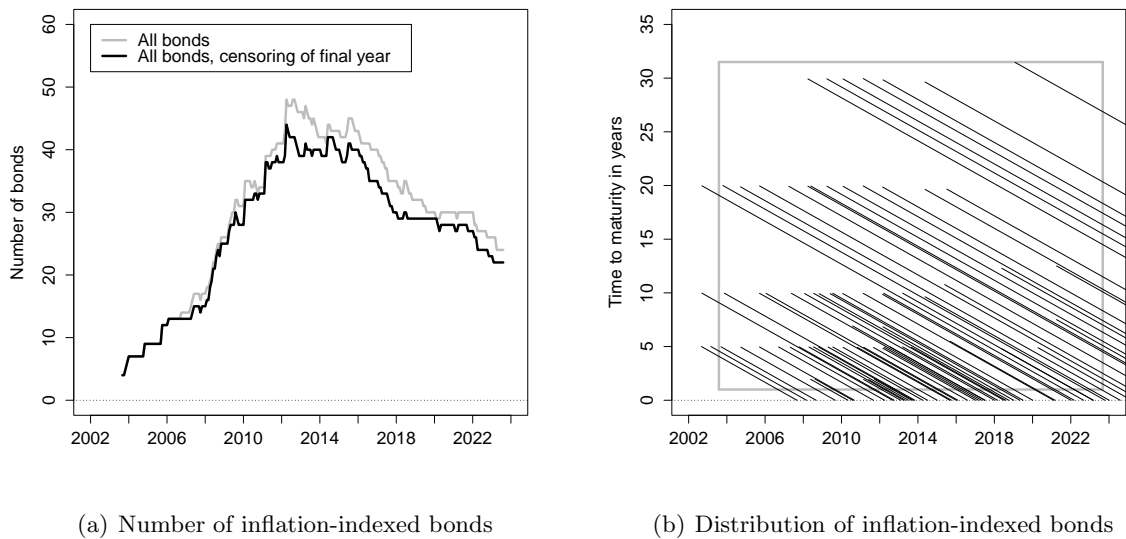

Figure 2: **Overview of the Chilean Inflation-Indexed Bond Data**

Panel (a) reports the number of outstanding inflation-indexed bonds at a given point in time. Panel (b) shows the maturity distribution of all inflation-indexed bonds issued since 2002. The solid gray rectangle indicates the sample used in our analysis, where the sample is restricted to start on August 31, 2003, and limited to inflation-indexed bond prices with more than one year to maturity after issuance.

in their payoffs. Therefore, to facilitate model estimation, we drop inflation-indexed bonds from our sample when they have less than one year to maturity. Using this cutoff, the number of bonds in the sample is modestly reduced, as shown with a solid black line in Figure 2(a). Finally, online Appendix A contains the contractual details of all 72 BTUs in our data as well as the number of monthly observations for each.

Since the early 2000s the Chilean government has issued a variety of inflation-indexed bonds with original maturities ranging from 2 years to 31 years. The maturity distribution of the 72 bonds in our sample is shown in Figure 2(b). Each bond is represented by a single downward-sloping line that plots its remaining years to maturity for each date. For the five- to ten-year maturities of particular interest for our analysis, the universe of bonds provides good coverage throughout our sample.

Figure 3 shows the yield-to-maturity series for all inflation-indexed bonds in our sample at the end of each month from August 2003 to July 2023. Note the following regarding these yield series. First, the significant persistent decline in real yields over the first 18 years of the sample is clearly visible, as is the rapid retracing of those declines during the last two years of the sample. Chilean long-term real yields were above 4 percent in the early 2000s and had dropped to near zero by late 2020. Second, business cycle variation in the shape of the yield curve is pronounced around these trends. The yield curve tends to flatten ahead of recessions

Figure 3: Yield to Maturity of Chilean Inflation-Indexed Bonds

Illustration of the yield to maturity implied by the Chilean government inflation-indexed bond prices considered in this paper, which are subject to two sample choices: (1) sample limited to the period from August 31, 2003, to July 31, 2023; (2) censoring of a bond’s price when it has less than one year to maturity. Each bond yield series is shown with its own colored line.

and steepen during the initial phase of economic recoveries. These characteristics are the practical motivation behind our choice of using a three-factor model for the frictionless part of the Chilean yield curve, adopting an approach similar to what is standard for U.S. and U.K. nominal yield data; see Christensen and Rudebusch (2012).

To support that choice more formally, we note that researchers have typically found that three factors are sufficient to model the time variation in the cross section of U.S. Treasury yields (e.g., Litterman and Scheinkman 1991). To perform a similar analysis based on our sample of Chilean inflation-indexed bond prices, we construct synthetic zero-coupon bond yields by fitting the flexible Svensson (1995) yield curve to the set of inflation-indexed bond prices observed for each observation date.¹⁰ To have a yield panel representative of the underlying bonds in our sample, we include yields for seven constant maturities: 2, 3, 5, 7, 10, 15, and 20 years. The data series are daily, covering the period from August 1, 2003, to July 31, 2023.

The result of a principal components analysis of the yield panel is reported in Table 1. The top panel reports the eigenvectors that correspond to the first three principal components. The first principal component accounts for 88.2 percent of the variation in the bond yields, and its loading across maturities is uniformly positive. Thus, similar to a level factor, a

¹⁰Technically, we proceed as described in Andreasen et al. (2019).

Maturity in months	First P.C.	Second P.C.	Third P.C.
24	0.46	0.64	-0.58
36	0.41	0.34	0.44
60	0.37	0.03	0.50
84	0.36	-0.14	0.26
120	0.35	-0.28	-0.01
180	0.35	-0.40	-0.23
240	0.34	-0.46	-0.32
% explained	88.20	9.91	1.73

Table 1: **Factor Loadings of Chilean Inflation-Indexed Bond Yields**

The top rows show the eigenvectors corresponding to the first three principal components (PC). Put differently, they show how bond yields at various maturities load on the first three principal components. In the final row the proportion of all bond yield variability explained by each principal component is shown. The data are daily Chilean zero-coupon inflation-indexed bond yields from August 1, 2003, to July 31, 2023, a total of 5,075 observations for each yield series.

shock to this component changes all yields in the same direction irrespective of maturity. The second principal component accounts for 9.9 percent of the variation in these data and has sizable positive loadings for the shorter maturities and sizable negative loadings for the long maturities. Thus, similar to a slope factor, a shock to this component steepens or flattens the yield curve. Finally, the third component, which accounts for 1.7 percent of the variation, has a hump-shaped factor loading as a function of maturity, which is naturally interpreted as a curvature factor. These three factors combined account for 99.84 percent of the total variation. This motivates our choice to focus on the Nelson and Siegel (1987) model with its level, slope, and curvature factors for modeling this sample of Chilean inflation-indexed bond prices. However, for theoretical consistency, we use the arbitrage-free version of this class of models derived in Christensen et al. (2011). Furthermore, to explain the remaining variation in the bond yield data not accounted for by the level, slope, and curvature factors, we augment the model with a risk factor to allow for bond-specific liquidity risk premia using the approach described in ACR and detailed in Section 4. Importantly, we stress that the estimated state variables in our model are *not* identical to the principal component factors discussed here, but estimated through Kalman filtering.¹¹

3.1 Bid-Ask Spreads of Chilean Inflation-Indexed Government Bonds

To shed light on the trading frictions in the market for Chilean inflation-indexed bonds, we compute the average bid-ask spread of the bonds in our sample for the available period,

¹¹A number of recent papers use principal components as state variables. Joslin et al. (2011) is an early example.

Figure 4: Bid-Ask Spreads of Chilean Inflation-Indexed Bonds

Illustration of the average bid-ask spread of the Chilean government inflation-indexed bond prices considered in this paper. For each bond, the bid and ask prices are converted into yields to maturity and the difference calculated. The shown series is monthly covering the period from January 31, 2006, to July 31, 2023.

which starts in 2006. The resulting series is shown in Figure 4. There are two key takeaways. First, with an average level of bid-ask spreads of around 5.6 basis points, the trading of these securities is indeed associated with some amount of liquidity risk. Second, the occasional large spikes in the bid-ask spreads of inflation-indexed bonds is a sign that the liquidity risk of these securities can be elevated at times, and we want to account for that in our analysis.

The empirical question we are interested in is to what extent the decline in the inflation-indexed bond yields through the end of 2020 and the subsequent sharp reversal represent variation in the natural real rate or are driven by other factors such as term or other bond-specific liquidity risk premia.

4 Model Estimation and Results

In this section, we first describe how we model yields in a world without any frictions to trading. This model of frictionless dynamics is fundamental to our analysis. We then detail the augmented model that accounts for the liquidity premia in the inflation-indexed bond yields. This is followed by a description of the restrictions imposed to achieve econometric identification of this model and its estimation. We end the section with a brief summary of our estimation results.

4.1 A Frictionless Arbitrage-Free Model of Real Yields

To capture the fundamental or frictionless factors operating the Chilean real yield curve, we choose to focus on the tractable affine dynamic term structure model introduced in Christensen et al. (2011).¹²

In this arbitrage-free Nelson-Siegel (AFNS) model, the state vector is denoted by $X_t = (L_t, S_t, C_t)$, where L_t is a level factor, S_t is a slope factor, and C_t is a curvature factor. The instantaneous risk-free real rate is defined as

$$r_t = L_t + S_t. \quad (1)$$

The risk-neutral (or \mathbb{Q} -) dynamics of the state variables are given by the stochastic differential equations¹³

$$\begin{pmatrix} dL_t \\ dS_t \\ dC_t \end{pmatrix} = \begin{pmatrix} 0 & 0 & 0 \\ 0 & -\lambda & \lambda \\ 0 & 0 & -\lambda \end{pmatrix} \begin{pmatrix} L_t \\ S_t \\ C_t \end{pmatrix} dt + \Sigma \begin{pmatrix} dW_t^{L,\mathbb{Q}} \\ dW_t^{S,\mathbb{Q}} \\ dW_t^{C,\mathbb{Q}} \end{pmatrix}, \quad (2)$$

where Σ is the constant lower triangular covariance (or volatility) matrix. Based on this specification of the \mathbb{Q} -dynamics, zero-coupon real bond yields preserve the Nelson-Siegel factor loading structure as

$$y_t(\tau) = L_t + \left(\frac{1 - e^{-\lambda\tau}}{\lambda\tau} \right) S_t + \left(\frac{1 - e^{-\lambda\tau}}{\lambda\tau} - e^{-\lambda\tau} \right) C_t - \frac{A(\tau)}{\tau}, \quad (3)$$

where $\frac{A(\tau)}{\tau}$ is a convexity term that adjusts the functional form in Nelson and Siegel (1987) to ensure absence of arbitrage (see Christensen et al. 2011).

To complete the description of the model and to implement it empirically, we will need to specify the risk premia that connect these factor dynamics under the \mathbb{Q} -measure to the dynamics under the real-world (or physical) \mathbb{P} -measure. It is important to note that there are no restrictions on the dynamic drift components under the empirical \mathbb{P} -measure beyond the requirement of constant volatility. To facilitate empirical implementation, we use the essentially affine risk premium specification introduced in Duffee (2002). In the Gaussian framework, this specification implies that the risk premia Γ_t depend on the state variables; that is,

$$\Gamma_t = \gamma^0 + \gamma^1 X_t,$$

¹²Although the model is not formulated using the canonical form of affine term structure models introduced by Dai and Singleton (2000), it can be viewed as a restricted version of the canonical Gaussian model; see Christensen et al. (2011) for details.

¹³As discussed in Christensen et al. (2011), with a unit root in the level factor, the model is not arbitrage-free with an unbounded horizon; therefore, as is often done in theoretical discussions, we impose an arbitrary maximum horizon.

where $\gamma^0 \in \mathbf{R}^3$ and $\gamma^1 \in \mathbf{R}^{3 \times 3}$ contain unrestricted parameters.

Thus, the resulting unrestricted three-factor AFNS model has \mathbb{P} -dynamics given by

$$\begin{pmatrix} dL_t \\ dS_t \\ dC_t \end{pmatrix} = \begin{pmatrix} \kappa_{11}^{\mathbb{P}} & \kappa_{12}^{\mathbb{P}} & \kappa_{13}^{\mathbb{P}} \\ \kappa_{21}^{\mathbb{P}} & \kappa_{22}^{\mathbb{P}} & \kappa_{23}^{\mathbb{P}} \\ \kappa_{31}^{\mathbb{P}} & \kappa_{32}^{\mathbb{P}} & \kappa_{33}^{\mathbb{P}} \end{pmatrix} \left(\begin{pmatrix} \theta_1^{\mathbb{P}} \\ \theta_2^{\mathbb{P}} \\ \theta_3^{\mathbb{P}} \end{pmatrix} - \begin{pmatrix} L_t \\ S_t \\ C_t \end{pmatrix} \right) dt + \Sigma \begin{pmatrix} dW_t^{L,\mathbb{P}} \\ dW_t^{S,\mathbb{P}} \\ dW_t^{C,\mathbb{P}} \end{pmatrix}.$$

This is the transition equation in the Kalman filter estimation.

4.2 An Arbitrage-Free Model of Real Yields with Liquidity Risk

In this section, we augment the frictionless model introduced above to account for the liquidity premium of the inflation-indexed bond prices we use in the empirical analysis. To do so, let $X_t = (L_t, S_t, C_t, X_t^{liq})$ denote the state vector of the four-factor model with liquidity risk premium adjustment that we refer to it as the AFNS-L model. As in the non-augmented model, we let the frictionless instantaneous real risk-free rate be defined by equation (1), while the risk-neutral dynamics of the state variables used for pricing are given by

$$\begin{pmatrix} dL_t \\ dS_t \\ dC_t \\ dX_t^{liq} \end{pmatrix} = \begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & \lambda & -\lambda & 0 \\ 0 & 0 & \lambda & 0 \\ 0 & 0 & 0 & \kappa_{liq}^{\mathbb{Q}} \end{pmatrix} \left[\begin{pmatrix} 0 \\ 0 \\ 0 \\ \theta_{liq}^{\mathbb{Q}} \end{pmatrix} - \begin{pmatrix} L_t \\ S_t \\ C_t \\ X_t^{liq} \end{pmatrix} \right] dt + \Sigma \begin{pmatrix} dW_t^{L,\mathbb{Q}} \\ dW_t^{S,\mathbb{Q}} \\ dW_t^{C,\mathbb{Q}} \\ dW_t^{liq,\mathbb{Q}} \end{pmatrix},$$

where Σ continues to be a lower triangular matrix.

In the augmented AFNS-L model, inflation-indexed bonds are sensitive to bond-specific liquidity risks as the net present value of their future cash flow is calculated using the following discount function:

$$\bar{r}^i(t, t_0^i) = r_t + \beta^i (1 - e^{-\lambda^{R,i}(t-t_0^i)}) X_t^{liq} = L_t + S_t + \beta^i (1 - e^{-\lambda^{R,i}(t-t_0^i)}) X_t^{liq}. \quad (4)$$

CR show that the net present value of one unit of consumption paid by BTU bond i at time $t + \tau$ has the following exponential-affine form

$$\begin{aligned} P_t(t_0^i, \tau) &= E^{\mathbb{Q}} \left[e^{-\int_t^{t+\tau} \bar{r}^i(s, t_0^i) ds} \right] \\ &= \exp \left(B_1(\tau) L_t + B_2(\tau) S_t + B_3(\tau) C_t + B_4(t, t_0^i, \tau) X_t^{liq} + A(t, t_0^i, \tau) \right). \end{aligned}$$

This result implies that the model belongs to the class of Gaussian affine term structure models. Note also that, by fixing $\beta^i = 0$ for all i , we recover the AFNS model.

Now, consider the whole value of bond i issued at time t_0^i with maturity at $t + \tau^i$ that

pays an annual coupon C^i semiannually. Its price is given by¹⁴

$$P_t(t_0^i, \tau^i, C^i) = C^i(t_1 - t)E^{\mathbb{Q}}\left[e^{-\int_t^{t_1} \bar{r}^i(s, t_0^i) ds}\right] + \sum_{j=2}^N \frac{C^i}{2} E^{\mathbb{Q}}\left[e^{-\int_t^{t_j} \bar{r}^i(s, t_0^i) ds}\right] \\ + E^{\mathbb{Q}}\left[e^{-\int_t^{t+\tau^i} \bar{r}^i(s, t_0^i) ds}\right].$$

Unlike U.S. TIPS, Chilean inflation-indexed bonds have no embedded deflation protection option, which makes their pricing straightforward. There is only one minor omission in the bond pricing formula above. It does not account for the lag in the inflation indexation of the bond payoff. The potential error from this omission should be modest (see Grishchenko and Huang 2013), especially as we exclude bonds from our sample when they have less than one year remaining to maturity.

Finally, to complete the description of the AFNS-L model, we again specify an essentially affine risk premium structure, which implies that the risk premia Γ_t take the form

$$\Gamma_t = \gamma^0 + \gamma^1 X_t,$$

where $\gamma^0 \in \mathbf{R}^4$ and $\gamma^1 \in \mathbf{R}^{4 \times 4}$ contain unrestricted parameters. Thus, the resulting unrestricted four-factor AFNS-L model has \mathbb{P} -dynamics given by

$$\begin{pmatrix} dL_t \\ dS_t \\ dC_t \\ dX_t^{liq} \end{pmatrix} = \begin{pmatrix} \kappa_{11}^{\mathbb{P}} & \kappa_{12}^{\mathbb{P}} & \kappa_{13}^{\mathbb{P}} & \kappa_{14}^{\mathbb{P}} \\ \kappa_{21}^{\mathbb{P}} & \kappa_{22}^{\mathbb{P}} & \kappa_{23}^{\mathbb{P}} & \kappa_{24}^{\mathbb{P}} \\ \kappa_{31}^{\mathbb{P}} & \kappa_{32}^{\mathbb{P}} & \kappa_{33}^{\mathbb{P}} & \kappa_{34}^{\mathbb{P}} \\ \kappa_{41}^{\mathbb{P}} & \kappa_{42}^{\mathbb{P}} & \kappa_{43}^{\mathbb{P}} & \kappa_{44}^{\mathbb{P}} \end{pmatrix} \left(\begin{pmatrix} \theta_1^{\mathbb{P}} \\ \theta_2^{\mathbb{P}} \\ \theta_3^{\mathbb{P}} \\ \theta_4^{\mathbb{P}} \end{pmatrix} - \begin{pmatrix} L_t \\ S_t \\ C_t \\ X_t^{liq} \end{pmatrix} \right) dt + \Sigma \begin{pmatrix} dW_t^{L, \mathbb{P}} \\ dW_t^{S, \mathbb{P}} \\ dW_t^{C, \mathbb{P}} \\ dW_t^{liq, \mathbb{P}} \end{pmatrix}.$$

This is the transition equation in the Kalman filter estimation.

4.3 Model Estimation and Econometric Identification

Due to the nonlinear relationship between the state variables and the bond prices, the model cannot be estimated with the standard Kalman filter. Instead, we use the extended Kalman filter as in Kim and Singleton (2012); see CR for details. Furthermore, to make the fitted errors comparable across bonds of various maturities, we scale each bond price by its duration. Thus, the measurement equation for the bond prices takes the following form

$$\frac{P_t^i(t_0^i, \tau^i)}{D_t^i(t_0^i, \tau^i)} = \frac{\widehat{P}_t^i(t_0^i, \tau^i)}{D_t^i(t_0^i, \tau^i)} + \varepsilon_t^i,$$

¹⁴This is the clean price that does not account for any accrued interest and maps to our observed bond prices.

where $\widehat{P}_t^i(t_0^i, \tau^i)$ is the model-implied price of bond i and $D_t^i(t_0^i, \tau^i)$ is its duration, which is calculated before estimation. See Andreasen et al. (2019) for evidence supporting this formulation of the measurement equation.

Furthermore, since the liquidity risk factor is a latent factor that we do not observe, its level is not identified without additional restrictions. As a consequence, we let the first 20-year inflation-indexed bond in our sample have a unit loading on this factor, that is, the 20-year inflation-indexed bond issued on September 11, 2002, and maturing on September 1, 2022, with 5 percent coupon has $\beta^i = 1$. This choice implies that the β^i sensitivity parameters measure liquidity risk sensitivity relative to that of the 20-year 2022 bond.

Finally, we note that the $\lambda^{L,i}$ parameters can be hard to identify if their values are too large or too small. As a consequence, we follow ACR and impose the restriction that they fall within the range from 0.01 to 10, which is without practical consequences as demonstrated by Christensen et al. (2021) in the context of Mexican bonos. Also, for numerical stability during model optimization, we impose the restriction that the β^i parameters fall within the range from 0 to 100, which turns out not to be a binding constraint in optimum.

4.4 Estimation Results

This section presents our benchmark estimation results. In the interest of simplicity, in this section we focus on a version of the AFNS-L model where $K^{\mathbb{P}}$ and Σ are diagonal matrices. As shown in ACR, these restrictions have hardly any effects on the estimated bond-specific liquidity risk premium for each inflation-indexed bond, because it is identified from the model's \mathbb{Q} -dynamics, which is independent of $K^{\mathbb{P}}$ and only display a weak link to Σ through the small convexity adjustment in yields. Furthermore, we stress that we relax this assumption in Section 6 when we analyze estimates of r_t^* , which are indeed sensitive to the specification of the models' \mathbb{P} -dynamics.

Tables 2 and 3 report the summary statistics for the fitted errors of individual inflation-indexed bonds as well as for all bonds combined. With the two exceptions of bonds number 27 and 40 in our sample, there is otherwise uniform improvement in model fit from incorporating the bond-specific liquidity risk factor into the AFNS model. Still, it is worth noting that the AFNS model is able to deliver a root mean-squared fitted error of 8.1 basis points across all bonds combined, which in general could be characterized as a satisfactory fit, but obviously not as good as the RMSE of 5.8 basis points for all bonds combined achieved by the AFNS-L model, which represents a really good fit to the entire cross section of yields. Note also that neither 20- nor 30-year bonds pose any particular challenges for the two models. Thus, both the AFNS and AFNS-L models are clearly able to fit those long-term bond yields to a satisfactory level of accuracy.¹⁵

¹⁵See Christensen et al. (2022) for an analysis of such long-term bond yields.

Table 2: **Pricing Errors and Estimated Bond-Specific Risk Parameters**

This table reports the mean pricing errors (Mean) and the root mean-squared pricing errors (RMSE) of Chilean inflation-indexed bonds in the AFNS and AFNS-L models estimated with a diagonal specification of $K^{\mathbb{P}}$ and Σ . The errors are computed as the difference between the inflation-indexed bond market price expressed as yield to maturity and the corresponding model-implied yield. All errors are reported in basis points. Standard errors (SE) are not available (n.a.) for the normalized value of β^3 .

Table 4: **Estimated Dynamic Parameters**

The table shows the estimated dynamic parameters for the AFNS and AFNS-L models estimated with a diagonal specification of $K^{\mathbb{P}}$ and Σ .

Table 4 contains the estimated dynamic parameters. With the exception of the slope factor, which is notably more persistent and less volatile in the AFNS-L model, the dynamics of the first three factors are qualitatively very similar across the two estimations. Furthermore, λ is marginally smaller in the AFNS-L model. This implies that the yield loading of the slope factor decays toward zero at a slightly lower pace as maturity increases. At the same time, the peak of the curvature yield loadings is located at a later maturity. As a consequence, slope and curvature matter somewhat more for longer-term yields in the AFNS-L model.

The estimated paths of the level, slope, and curvature factors from the two models are shown in Figure 5. The two models' slope and curvature factors are fairly close to each other during the entire sample, while there is a notable persistent difference between the two estimated level factors. Accordingly, the main impact of accounting for bond-specific liquidity premia in the pricing of the inflation-indexed bonds is on the level of the frictionless real yield curve. The fourth factor in the AFNS-L model, the bond-specific liquidity risk factor, is a stationary quickly mean-reverting process without any pronounced persistent changes, although it did experience a large increase during the last year of the sample. Based on its historical pattern this outsized spike could be expected to be short-lived.

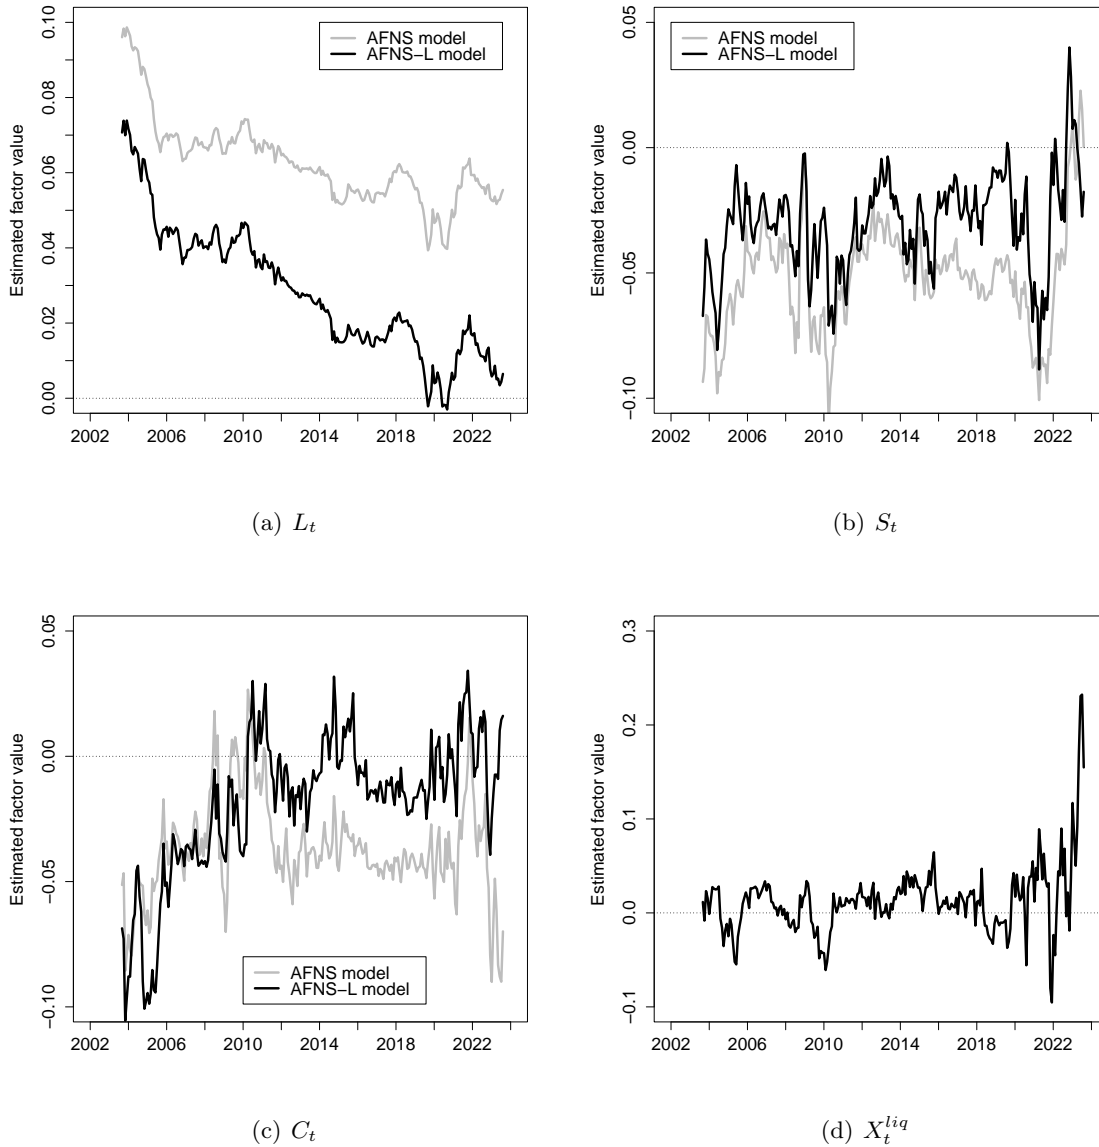

Figure 5: **Estimated State Variables**

Illustration of the estimated state variables from the AFNS and AFNS-L models. In each figure, the shown data cover the period from August 31, 2003, to July 31, 2023.

5 The Inflation-Indexed Bond Liquidity Premia

In this section, we analyze the inflation-indexed bond-specific liquidity premia implied by the estimated AFNS-L model described in the previous section. First, we formally define the bond-specific liquidity risk premia and study their historical evolution. We then assess the robustness of their estimation to various model and sample assumptions before we use regression analysis to examine their determinants.

5.1 The Estimated Inflation-Indexed Bond Liquidity Premia

We now use the estimated AFNS-L model to extract the liquidity premia in the Chilean inflation-indexed bond market. To compute these premia, we first use the estimated parameters and the filtered states $\{X_{t|t}\}_{t=1}^T$ to calculate the fitted inflation-indexed bond prices $\{\hat{P}_t^i\}_{t=1}^T$ for all outstanding securities in our sample. These bond prices are then converted into yields to maturity $\{\hat{y}_t^{c,i}\}_{t=1}^T$ by solving the fixed-point problem

$$\begin{aligned} \hat{P}_t^i &= C(t_1 - t) \exp\left\{-(t_1 - t)\hat{y}_t^{c,i}\right\} + \sum_{k=2}^n \frac{C}{2} \exp\left\{-(t_k - t)\hat{y}_t^{c,i}\right\} \\ &\quad + \exp\left\{-(T - t)\hat{y}_t^{c,i}\right\}, \end{aligned} \quad (5)$$

for $i = 1, 2, \dots, n_t$, meaning that $\{\hat{y}_t^{c,i}\}_{t=1}^T$ is approximately the real rate of return on the i th bond if held until maturity (see Sack and Elsasser 2004). To obtain the corresponding yields with correction for the liquidity risk, we compute a new set of model-implied bond prices from the estimated AFNS-L model using only its frictionless part, i.e., using the constraints that $X_{t|t}^{liq} = 0$ for all t as well as $\sigma_{44} = 0$ and $\theta_{liq}^Q = 0$. These prices are denoted $\{\tilde{P}_t^i\}_{t=1}^T$ and converted into yields to maturity $\tilde{y}_t^{c,i}$ using equation (5). They represent estimates of the prices that would prevail in a world without any financial frictions. The liquidity premium for the i th bond is then defined as

$$\Psi_t^i \equiv \hat{y}_t^{c,i} - \tilde{y}_t^{c,i}. \quad (6)$$

Figure 6 shows the average inflation-indexed bond liquidity premium $\bar{\Psi}_t$ across the outstanding bonds at each point in time. Although strictly positive as one could expect of a risk premium, the average estimated liquidity premium varies notably over time with a maximum of 303 basis points in summer 2023 and a low of 50 basis points in late 2021, when inflation had spiked to multidecade highs in Chile and much of the rest of the world. For the entire period it has an average of 111.73 basis points with a standard deviation of 31.09 basis points. Thus, liquidity premia represent a notable component in Chilean real yields as anticipated by the structural arguments laid out in Cardozo and Christensen (2024).

These results can be compared to those of ACR, who report that the average liquidity premium in U.S. TIPS is estimated at 34 basis points for the 1997-2013 period. The difference in liquidity premium levels across the TIPS and the Chilean inflation-indexed bond markets is likely to be due to the much greater relative liquidity of U.S. Treasury securities. Beauregard et al. (2024) report average estimated liquidity premia for Mexican inflation-indexed bonds, also known as udibonos, around 47 basis points during the 2009-2019 period. In contrast,

Figure 6: **Average Estimated Inflation-Indexed Bond Liquidity Premium**

Illustration of the average estimated inflation-indexed bond liquidity premium for each observation date implied by the AFNS-L model. The inflation-indexed bond liquidity premia are measured as the estimated yield difference between the fitted yield to maturity of individual inflation-indexed bonds and the corresponding frictionless yield to maturity with the liquidity risk factor turned off. The data cover the period from August 31, 2003, to July 31, 2023.

Cardozo and Christensen (2024) report estimated liquidity premia for Colombian inflation-indexed bonds, so-called bonos UVR, that average 243 basis points with a standard deviation of 27 basis points during the 2005-2020 period. Overall, we take these results to imply that our estimated liquidity premia for Chilean inflation-indexed bonds are of reasonable size and fall within the range of estimates reported for other comparable markets of inflation-indexed bonds.

5.2 Robustness Analysis

This section examines the robustness of the average liquidity premium reported in the previous section to some of the main assumptions imposed so far. Throughout the section, the AFNS-L model with diagonal $K^{\mathbb{P}}$ and Σ matrices serves as the benchmark for the reasons already listed in Section 4.4.

First, we assess whether the specification of the dynamics within the AFNS-L model matters for the estimated Chilean inflation-indexed bond liquidity premium. To do so, we estimate the AFNS-L model with unconstrained dynamics, that is, the AFNS-L model with unrestricted $K^{\mathbb{P}}$ and lower triangular Σ matrix. Figure 7 shows the estimated inflation-

Figure 7: **Average Estimated Inflation-Indexed Bond Liquidity Premium: Alternative \mathbb{P} Dynamics**

Illustration of the average estimated inflation-indexed bond liquidity premium for each observation date implied by the AFNS-L model when estimated with unconstrained dynamics as detailed in the text instead of independent factor dynamics. In both cases, the inflation-indexed bond liquidity premia are measured as the estimated yield difference between the fitted yield to maturity of individual inflation-indexed bonds and the corresponding frictionless yield to maturity with the liquidity risk factor turned off.

indexed liquidity premium from this estimation and compares it to the series produced by our benchmark model. Note that they are highly positively correlated and only marginally higher in the unconstrained model. Thus, we conclude that the specification of the dynamics within the AFNS-L model plays only a modest role for the estimated bond-specific liquidity risk premia, which is consistent with the findings of ACR in the context of U.S. TIPS.

Second, we assess whether the data frequency plays any role for our results. To do so, we estimate the AFNS-L model using daily, weekly, and monthly data; based on the results above, it suffices to focus on the most parsimonious AFNS-L model with diagonal $K^{\mathbb{P}}$ and Σ matrices. Figure 8 shows the estimated inflation-indexed bond liquidity premium series from the three estimations. Note that they are all very close to each other. Thus, we conclude that data frequency matters little for our results. Clearly, at the higher daily and weekly frequencies, there are some isolated sharp spikes that are absent in the monthly series, but they are too infrequent and short-lived to have an impact on the estimation results.

Figure 8: **Average Estimated Inflation-Indexed Bond Liquidity Premium: Data Frequency**

Illustration of the average estimated inflation-indexed bond liquidity premium for each observation date implied by the AFNS-L model when estimated using daily, weekly, and monthly data. In all three cases, the inflation-indexed bond liquidity premia are measured as the estimated yield difference between the fitted yield to maturity of individual inflation-indexed bonds and the corresponding frictionless yield to maturity with the liquidity risk factor turned off.

5.3 Regression Analysis

In this section, we use regression analysis to determine the key factors driving the variation in the average estimated inflation-indexed bond liquidity premium series.

For the structural reasons described in Cardozo and Christensen (2024), the trading of inflation-indexed bonds is likely to be dominated by patient domestic buy-and-hold investors. This is also the explanation why the steady state of the market for these bonds is one associated with bond prices being lower due to the sizable liquidity premium discounts documented above. We speculate that increased holdings by this group of investors should make it harder for investors to sell the bonds back to the market if hit with an unexpected liquidity shock. This should make investors demand a higher liquidity premium for assuming the higher risk, all else being equal. To test this conjecture, our key explanatory variable is the pension fund share defined as Chilean pension fund holdings of inflation-indexed bonds divided by the total outstanding amount of inflation-indexed bonds. We consider this a proxy for the holdings of all domestic buy-and-hold investors in Chile.

Second and relatedly, the size of the inflation-indexed bond market should matter for the

Explanatory variables	(1)	(2)	(3)	(4)	(5)
Pension fund share	4.74*** (1.45)	2.35* (1.25)	4.16*** (1.10)	3.08*** (0.98)	3.08*** (0.99)

Liquidity controls		Yes			Yes
Risk sentiment controls			Yes		Yes
Domestic macro controls				Yes	Yes
Intercept	-21.35 (39.04)	23.33 (66.82)	-24.60 (32.43)	47.95 (52.68)	11.05 (66.83)
Adjusted R^2	0.20	0.32	0.38	0.45	0.49

Table 5: **Regression Results for the Average Estimated Inflation-Indexed Bond Liquidity Premium**

The table reports the results of regressions with the average estimated inflation-indexed bond liquidity risk premium as the dependent variable and a total of 16 explanatory variables as explained in the main text. Standard errors computed by the Newey-West estimator (with three lags) are reported in parentheses. Asterisks *, ** and *** indicate significance at the 10 percent, 5 percent and 1 percent levels, respectively.

liquidity risk premium investors demand for assuming the liquidity risk of these bonds. We conjecture that, if the market size increases, the liquidity premia should decline, all else being equal. To test this hypothesis, we use the monthly total outstanding amount of inflation-indexed bonds scaled by nominal GDP.

In Table 5, column (1) reports the result of using these two variables to explain the variation in the average estimated inflation-indexed liquidity premium series. We note that we get a significant positive coefficient on the pension fund share confirming our conjecture and that of Christensen and Cardozo (2024), that is, as the market becomes more dominated by buy-and-hold investors, its steady state moves towards one of increasing liquidity premia. At the same time, we get a significant negative coefficient on the indexed BTU market-to-GDP ratio. This means that an expansion of the inflation-indexed bond market relative to GDP tends to put downward pressure on inflation-indexed bond liquidity premia—a positive effect of increased supply. Hence, positive effects from an expansion of the market relative to the size of the economy may be offset provided the extra bond volume is acquired by domestic buy-and-hold investors.

To verify the robustness of these findings, we consider several groups of control variables.¹⁶

To begin, we are interested in the role of factors that are believed to matter for inflation-indexed bond market liquidity specifically. These variables include the average bid-ask spread in the inflation-indexed bond market, the average inflation-indexed bond age, the one-month realized volatility of the ten-year inflation-indexed bond yield, a noise measure of the bond prices to control for variation in the amount of arbitrage capital available in this market, and the inflation-indexed bond market turnover. Adding these five control variables tied to bond market liquidity and functioning produces the results reported in regression (2) in Table 5. We note an increase in the adjusted R^2 to 0.32. Our two key explanatory variables preserve their statistically significant coefficients, even though they are somewhat smaller in size.

After having explored the role of liquidity factors, we examine the effects of factors reflecting risk sentiment on the inflation-indexed liquidity premium series. These variables include the VIX, the U.S. Treasury ten-year on-the-run premium, the J.P. Morgan Emerging Market Bond Index (EMBI), the five-year credit default swap (CDS) rate for Chile, and the MOVE index. The results of the regression with these five added control variables are reported in regression (3) in Table 5. We note an increase in the adjusted R^2 to 0.38. Importantly, our two key explanatory variables preserve their significant coefficients as in the original regression.

In the final group, we assess the role played by standard domestic macro variables for the inflation-indexed liquidity risk premium series. These include the year-over-year change in the Chilean CPI, the economic policy uncertainty (EPU) in Chile, the Chilean monetary policy rate, and a measure of the relative prices of traded goods for the Chilean economy proxied by the log ratio of copper prices over the West Texas Intermediate (WTI) Cushing crude oil price. The results of the regression with these four standard macroeconomic control variables are reported in regression (4) in Table 5. It produces a high adjusted R^2 of 0.45. Still, our two key explanatory variables remain statistically significant.

To assess the robustness of the results from the first four regressions, we include all variables with the results reported in column (5) in Table 5. Although this joint regression produces a high adjusted R^2 of 0.49, the results reported in online Appendix B shows that none of the control variables are statistically significant at the 5 percent level. More importantly, our two key explanatory variables remain statistically significant and preserve both their sign and approximate magnitudes as in the earlier regressions. As a consequence, we consider our findings to be robust.

Related to our findings we note that the presence of large institutional investors and their influence on domestic markets have been extensively documented as pivotal drivers of liquidity and risk premia; see Pritsker (2002) and Vayanos and Vila (2021), among many others. In the context of Chile, the main investors in the domestic government fixed-income

¹⁶See online Appendix B for a full description of the explanatory variables and the full regression results.

markets are so-called pension fund administrators. As of June 2023, this group of investors held nearly 70 percent of the total stock of BTUs. The strong significance of the coefficient on their market share in our regressions is likely to be explained by the buy-and-hold investment approach followed by these funds, along with their preference for longer-maturity bonds. Furthermore, we evaluate the impact of the size of the domestic bond market—proxied by the total outstanding bonds relative to GDP—on the bond liquidity premia. Following the onset of the COVID-19 pandemic, there has been a reduction in the size of the domestic bond market, declining from 13 percent of GDP in the 2013-2019 period to 10 percent of GDP in the post-pandemic era. During the same period, there are matching changes in our proxies for bond liquidity such as lower bond market turnover and increased bid-ask spreads.

In terms of the interpretation of the estimated coefficients in the regression with all variables, our results suggest that a 1 percentage point increase in the pension fund market share is correlated with an increase of 3 basis points in our bond liquidity premium series. In contrast, a 1 percentage point increase in the BTU market size relative to GDP is associated with a decline of about 9 basis points in the bond liquidity premium series. Thus, the overall size of the market seems to matter more than the distribution of the market shares, or put differently, the negative impact on BTU market liquidity from an increase in investor concentration can be overcome through an expansion of the market, in particular if the new issuance is acquired by investors pursuing active trading strategies such as hedge funds or foreign investors, although we admit that this is a challenging outcome to achieve given the intrinsic trading dynamics in this market tilt towards static buy-and-hold investors.

Finally, to the best of our knowledge, ours is the first study to document a clear connection between the size of liquidity premia in an established inflation-indexed bond market on one hand and the concentration of the holdings of domestic buy-and-hold investors on the other. In addition to helping explain why inflation-indexed bonds in Chile and elsewhere tend to trade with large liquidity discounts, it provides support for the explanation for this phenomenon offered by Cardozo and Christensen (2024). Moreover, we believe a similar kind of analysis in the context of the U.S. TIPS market could go a long way towards solving the TIPS-Treasury bond pricing puzzle highlighted in the influential paper by Fleckenstein et al. (2014), but we leave it for future research to explore that conjecture further.

6 A New Normal for Chilean Interest Rates?

In this section, we first introduce our market-based definition of the natural real rate before we go through a careful model selection process to find a preferred specification of the AFNS-L model’s objective \mathbb{P} -dynamics. We then use this AFNS-L model to account for liquidity and term premia in the inflation-indexed bond prices and obtain expected real short rates

and the associated measure of the equilibrium real rate. Finally, we compare this estimate to other market- and macro-based estimates from the literature and consider the persistence of forces that may be pushing the real rate lower in Chile.

6.1 Definition of the Natural Rate

Our working definition of the equilibrium real rate of interest r_t^* is

$$r_t^* = \frac{1}{5} \int_{t+5}^{t+10} E_t^{\mathbb{P}}[r_s] ds, \quad (7)$$

that is, the average expected real short rate over a five-year period starting five years ahead where the expectation is with respect to the objective \mathbb{P} -probability measure. As explained in CR, this 5yr5yr forward average expected real short rate should be little affected by short-term transitory shocks. Alternatively, r_t^* could be defined as the expected real short rate at an infinite horizon. However, this quantity will depend crucially on whether the factor dynamics exhibit a unit root. As is well known, the typical spans of time series data that are available do not distinguish strongly between highly persistent stationary processes and nonstationary ones. Our model follows the finance literature and adopts the former structure, so strictly speaking, our infinite-horizon steady-state expected real rate is constant. However, we do not view our data sample as having sufficient information in the 10-year to infinite horizon range to definitively pin down that steady state, so we prefer our definition with a medium- to long-run horizon.

6.2 Model Selection

For estimation of the natural real rate and associated real term premia, the specification of the mean-reversion matrix $K^{\mathbb{P}}$ is critical, as noted earlier. To select the best fitting specification of the model's real-world dynamics, we use a general-to-specific modeling strategy in which the least significant off-diagonal parameter of $K^{\mathbb{P}}$ is restricted to zero and the model is re-estimated. This strategy of eliminating the least significant coefficient starts from the AFNS-L model with an unrestricted $K^{\mathbb{P}}$ matrix and is carried out down to the most parsimonious specification, which has a diagonal $K^{\mathbb{P}}$ matrix. The final specification choice is based on the value of the Bayesian information criterion (BIC), as in Christensen et al. (2014).¹⁷

The summary statistics of the model selection process are reported in Table 6. The BIC

¹⁷The Bayesian information criterion is defined as $BIC = -2 \log L + k \log T$, where k is the number of model parameters and $T = 240$ is the number of monthly data observations.

Alternative specifications	Goodness of fit statistics			
	$\log L$	k	p -value	BIC
(1) Unrestricted $K^{\mathbb{P}}$	36,592.74	171	n.a.	-72,248.29
(2) $\kappa_{23}^{\mathbb{P}} = 0$	36,592.74	170	1.00	-72,253.77
(3) $\kappa_{23}^{\mathbb{P}} = \kappa_{14}^{\mathbb{P}} = 0$	36,592.66	169	0.69	-72,259.09
(4) $\kappa_{23}^{\mathbb{P}} = \kappa_{14}^{\mathbb{P}} = \kappa_{13}^{\mathbb{P}} = 0$	36,591.06	168	0.07	-72,261.37
(5) $\kappa_{23}^{\mathbb{P}} = \dots = \kappa_{34}^{\mathbb{P}} = 0$	36,590.40	167	0.25	-72,265.53
(6) $\kappa_{23}^{\mathbb{P}} = \dots = \kappa_{42}^{\mathbb{P}} = 0$	36,590.04	166	0.40	-72,270.29
(7) $\kappa_{23}^{\mathbb{P}} = \dots = \kappa_{24}^{\mathbb{P}} = 0$	36,585.05	165	< 0.01	-72,265.79
(8) $\kappa_{23}^{\mathbb{P}} = \dots = \kappa_{21}^{\mathbb{P}} = 0$	36,583.15	164	0.05	-72,267.48
(9) $\kappa_{23}^{\mathbb{P}} = \dots = \kappa_{43}^{\mathbb{P}} = 0$	36,582.26	163	0.18	-72,271.18
(10) $\kappa_{23}^{\mathbb{P}} = \dots = \kappa_{41}^{\mathbb{P}} = 0$	36,579.90	162	0.03	-72,271.94
(11) $\kappa_{23}^{\mathbb{P}} = \dots = \kappa_{12}^{\mathbb{P}} = 0$	36,572.27	161	< 0.01	-72,262.16
(12) $\kappa_{23}^{\mathbb{P}} = \dots = \kappa_{32}^{\mathbb{P}} = 0$	36,564.98	160	< 0.01	-72,253.06
(13) $\kappa_{23}^{\mathbb{P}} = \dots = \kappa_{31}^{\mathbb{P}} = 0$	36,559.58	159	< 0.01	-72,247.74

Table 6: **Evaluation of Alternative Specifications of the AFNS-L Model**

There are thirteen alternative estimated specifications of the AFNS-L model. Each specification is listed with its maximum log likelihood ($\log L$), number of parameters (k), the p -value from a likelihood ratio test of the hypothesis that it differs from the specification above with one more free parameter, and the Bayesian information criterion (BIC). The period analyzed covers monthly data from August 31, 2003, to July 31, 2023.

is minimized by specification (10), which has a $K^{\mathbb{P}}$ matrix given by

$$K_{BIC}^{\mathbb{P}} = \begin{pmatrix} \kappa_{11}^{\mathbb{P}} & \kappa_{12}^{\mathbb{P}} & 0 & 0 \\ 0 & \kappa_{22}^{\mathbb{P}} & 0 & 0 \\ \kappa_{31}^{\mathbb{P}} & \kappa_{32}^{\mathbb{P}} & \kappa_{33}^{\mathbb{P}} & 0 \\ 0 & 0 & 0 & \kappa_{44}^{\mathbb{P}} \end{pmatrix}.$$

The estimated parameters of the preferred specification are reported in Table 7. The estimated \mathbb{Q} -dynamics used for pricing and determined by $(\Sigma, \lambda, \kappa_{liq}^{\mathbb{Q}}, \theta_{liq}^{\mathbb{Q}})$ are very close to those reported in Table 4 for the AFNS-L model with diagonal $K^{\mathbb{P}}$. This implies that both model fit and the estimated inflation-indexed bond liquidity premia from the preferred AFNS-L model are very similar to those already reported and therefore not shown. Furthermore, the estimated objective \mathbb{P} -dynamics in terms of $\theta^{\mathbb{P}}$ and Σ are also qualitatively similar to those reported in Table 4. Finally, there are intriguing significant dynamic interactions between the level, slope, and curvature factors in our preferred specification. To understand the role played by the mean-reversion matrix $K^{\mathbb{P}}$ for estimates of the natural real rate, we will later on analyze the most flexible model with unrestricted mean-reversion matrix $K^{\mathbb{P}}$ and the most parsimonious model with diagonal $K^{\mathbb{P}}$ in addition to our preferred specification described above.

$K^{\mathbb{P}}$	$K^{\mathbb{P}}_{:,1}$	$K^{\mathbb{P}}_{:,2}$	$K^{\mathbb{P}}_{:,3}$	$K^{\mathbb{P}}_{:,4}$	$\theta^{\mathbb{P}}$		Σ
$K^{\mathbb{P}}_{1,}$	0.2745 (0.0546)	0.4016 (0.0518)	0	0	0.0607 (0.0146)	σ_{11}	0.0064 (0.0003)
$K^{\mathbb{P}}_{2,}$	0	0.4613 (0.0670)	0	0	-0.0591 (0.0128)	σ_{22}	0.0316 (0.0023)
$K^{\mathbb{P}}_{3,}$	3.9204 (0.0657)	2.0614 (0.0663)	2.5954 (0.0656)	0	-0.0441 (0.0154)	σ_{33}	0.0321 (0.0024)
$K^{\mathbb{P}}_{4,}$	0	0	0	1.6384 (0.0674)	0.0166 (0.0152)	σ_{44}	0.0734 (0.0045)

Table 7: **Estimated Dynamic Parameters of the Preferred AFNS-L Model**

The table shows the estimated parameters of the $K^{\mathbb{P}}$ matrix, $\theta^{\mathbb{P}}$ vector, and diagonal Σ matrix for the preferred AFNS-L model according to the BIC. The estimated value of λ is 0.3955 (0.0095), while $\kappa_{liq}^{\mathbb{Q}} = 3.2534$ (0.0677), and $\theta_{liq}^{\mathbb{Q}} = 0.0096$ (0.0004). The maximum log likelihood value is 36,579.90. The numbers in parentheses are the estimated parameter standard deviations.

6.3 Estimates of the Natural Rate

Our market-based measure of the natural rate is the average expected real short rate over a five-year period starting five years ahead. This 5yr5yr forward average expected real short rate should be little affected by short-term transitory shocks and well positioned to capture the persistent trends in the natural real rate.

To illustrate the decomposition underlying our definition of r_t^* , recall that the real term premium is defined as

$$TP_t(\tau) = y_t(\tau) - \frac{1}{\tau} \int_t^{t+\tau} E_t^{\mathbb{P}}[r_s] ds,$$

where $y_t(\tau)$ is the *frictionless* real yield with maturity at $t + \tau$. That is, the real term premium is the difference in expected real return between a buy-and-hold strategy for a τ -year real bond and an instantaneous rollover strategy at the risk-free real rate r_t . Figure 9 shows the AFNS-L model decomposition of the 5yr5yr forward frictionless real yield based on this equation. The solid green line is the 5yr5yr forward real term premium, which, although volatile, has fluctuated around a fairly stable level since the early 2000s. Although theory suggests that this premium is countercyclical and elevated during economic recessions, our estimates only partially align with these characteristics. In contrast, the estimate of the natural rate of interest implied by the AFNS-L model—the blue line—shows a gradual decline from around 0.5 percent in the early 2000s to below -2 percent by mid-2022. Importantly, it has remained low since then despite the recent large increases in bond yields. By the end of our sample, the estimate of r_t^* stands at -1.30 percent.

Equally important, note the sizable inflation-indexed bond liquidity premia that drive a large wedge between the observed 5yr5yr real yield shown with a solid black line and the lower 5yr5yr frictionless real yield shown with a solid gray line. Thus, without the liquidity

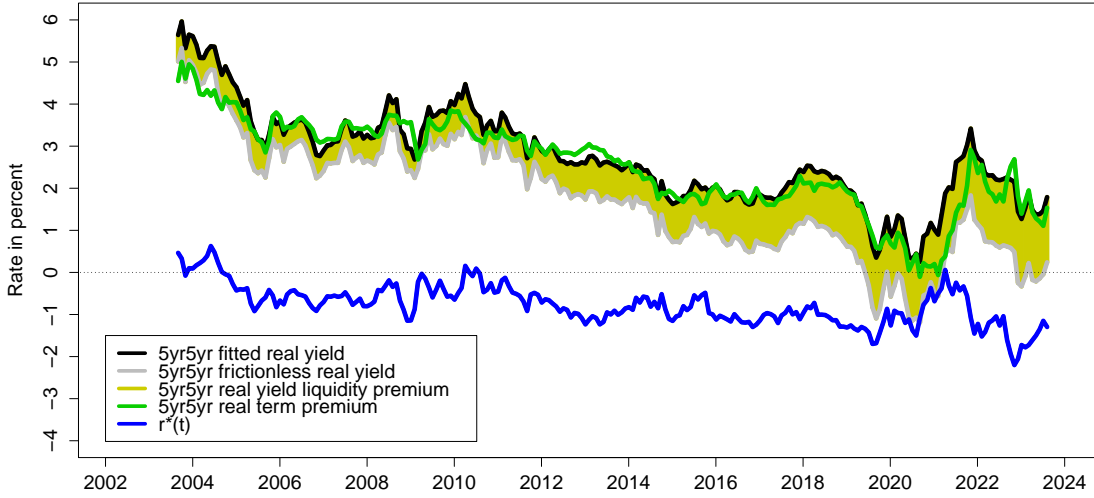

Figure 9: AFNS-L Model 5yr5yr Real Yield Decomposition

Illustration of the 5yr5yr fitted real yield calculated based on an AFNS model estimated using the sample of Chilean inflation-indexed government bond prices examined in this paper. Also shown is the estimated 5yr5yr frictionless real yield implied by the preferred AFNS-L model and its decomposition into the 5yr5yr expected real short rates, which is equivalent to our definition of r_t^* , and the residual 5yr5yr real term premium. Note that the difference between the fitted 5yr5yr real yield and the estimated 5yr5yr frictionless real yield equals the estimated 5yr5yr real yield liquidity premium. The data cover the period from August 31, 2003, to July 31, 2023.

premium adjustment, one might be led to believe that real yields are much higher than what is actually the case, a point also made by Andreasen and Christensen (2016) in the context of U.S. TIPS.

Finally, we note that, for the pandemic and post-pandemic period starting in early 2020 and running through the end of our sample in June 2023, our estimate of the natural real rate in Chile changed very little on net. Instead, the sizable increase in Chilean long-term real yields that is clearly visible in Figure 9 was accounted for mostly by a sharp increase in real term premia that brought them back to the level prevailing in the years before the pandemic, while the 5yr5yr real yield liquidity premium only experienced a modest increase during this period.

6.3.1 Sensitivity Analysis

To begin, we examine the sensitivity of our r_t^* estimate to our choice to define r_t^* as the average expected real short rate over a five-year period starting five years ahead. To that end, we consider two alternative definitions that both embed a longer view about the time it takes

Figure 10: **The Sensitivity of r^* Estimate to Alternative Definitions**

Illustration of the 5yr5yr expected real short rates, which is equivalent to our benchmark definition of r_t^* , implied by our preferred AFNS-L model. Also shown are two additional series using alternative definitions of r_t^* , namely a 7yr3yr approach and a 9yr1yr approach. In all three cases, the data cover the period from August 31, 2003, to July 31, 2023.

for the Chilean economy to reach steady state. The first assumes that this takes seven years and then measures the neutral real rate as the average expected real short over the following three years. It is referred to as the 7yr3yr r_t^* estimate. The second alternative takes an even longer view and assumes that it takes nine years to reach steady state and then measures the neutral real rate as the average expected real short rate over a short one-year period. It is referred to as the 9yr1yr r_t^* estimate. Figure 10 shows all three r_t^* estimates, which are highly positively correlated and very close to each other thanks to the high estimated persistence of the state variables within our preferred AFNS-L model. Hence, our r_t^* estimate of the neutral real rate in Chile has relatively little sensitivity to the specific definition of r_t^* used. Thus, our reported results are very robust from that perspective.

To assess the sensitivity of our r_t^* estimate to the specification of the mean-reversion matrix $K^{\mathbb{P}}$, we compare it in Figure 11 to the estimates from the AFNS-L models with unrestricted and diagonal $K^{\mathbb{P}}$ matrix, respectively. As can be seen from the figure, our r_t^* estimate is indeed somewhat sensitive to this model choice, but flexible specifications like our preferred AFNS-L model specification tend to give fairly similar r_t^* estimates. Note also that all three estimates are dominated by a persistent lower trend during the entire 20-year sample period.

The role of the data frequency is examined in Figure 12, which shows the r_t^* estimates

Figure 11: **The Sensitivity of r^* Estimates to $K^{\mathbb{P}}$ Specification**

Illustration of the 5yr5yr expected real short rates, which is equivalent to our definition of r_t^* , implied by our preferred AFNS-L model as well as those implied by the AFNS-L models with diagonal and unrestricted $K^{\mathbb{P}}$ matrices. In all three cases, the volatility matrix Σ is diagonal. The data cover the period from August 31, 2003, to July 31, 2023.

implied by our preferred AFNS-R model estimated at daily, weekly, and monthly frequency. The results show that our estimate has little sensitivity to our choice to focus on conventional monthly data to facilitate model estimation. However, these results demonstrate that it would be possible to use our model for high-frequency daily policy and market monitoring analysis.

6.4 Comparison of Estimates of the Natural Rate

In this section, we compare our estimate of the natural real rate to other existing estimates of the equilibrium or natural interest rate in the literature. To start, we compare the r_t^* estimate from our preferred AFNS-L model to an update through June 2024 of the Mexican market-based estimate reported by Beauregard et al. (2024, henceforth BCFZ) using a combination of Mexican nominal bond prices and prices of Mexican inflation-indexed bonds and to a similar Colombian market-based estimate calculated from an update through June 2024 of the analysis in Cardozo and Christensen (2024, henceforth CC). These three market-based estimates of the natural real rate are shown in Figure 13. The high positive correlation and similar downward trend between the Chilean and Colombian estimates are both evident. In contrast, the Mexican estimate has remained relatively stable and fluctuated around 2 percent over the past 15 years. Importantly, none of the estimates have been materially affected by

Figure 12: **The Sensitivity of r^* Estimates to Data Frequency**

Illustration of the 5yr5yr expected real short rates, which is equivalent to our definition of r_t^* , implied by our preferred AFNS-L model estimated with daily, weekly, and monthly data.

the COVID-19 pandemic or its aftermath. Similarly, the Global Financial Crisis of 2008-2009 also appears to have left at most modest prints on the r_t^* estimates from Chile and Colombia.

Now, we turn to the crucial comparison of our finance-based estimate of r_t^* with an estimate based on macroeconomic data. Figure 14 shows the r_t^* estimate from our preferred AFNS-L model along with the macro-based estimate of r^* from an implementation of the Holston et al. (2017, henceforth HLW) model using Chilean macro data by staff at the Central Bank of Chile.¹⁸ The macro-based estimate shown in the figure starts in 1988 before our yield data. Importantly, both series are characterized by persistent secular declines. For the overlapping period between 2003 and 2022, we note that the macro-based estimate is more volatile and assumes both the highest and the lowest values. Hence, our finance-based r_t^* estimate is entirely within the range of the macro-based estimate. Overall, we consider this evidence favorable to our yields-only approach to estimating r_t^* .

6.5 Projections of the Natural Rate

In light of the intense debate among researchers, investors, and policymakers about whether there is a new higher normal for interest rates, we end our analysis by presenting the outlook for the natural real rate in Chile based on the preferred AFNS-L model. We follow the

¹⁸This is the filtered estimate generated by applying the approach described in Laubach and Williams (2003) to Chilean macroeconomic series.

Figure 13: **Comparison with Foreign Market-Based Estimates of r^***

Illustration of the 5yr5yr expected real short rates, which is equivalent to our definition of r_t^* , implied by our preferred AFNS-L model of Chilean inflation-indexed government bond prices covering the period from August 31, 2003, to July 31, 2023. Also shown are the corresponding results for Colombia from an update of the model examined in Cardozo and Christensen (2024) with weekly data covering the period from January 7, 2005, to June 28, 2024, and for Mexico from an update of the model examined in Beauregard et al. (2024) with monthly data covering the period from May 31, 2009, to June 28, 2024.

approach of Christensen et al. (2015) and simulate 10,000 factor paths over a ten-year horizon conditioned on the shape of the inflation-indexed yield curve and investors' embedded forward-looking expectations as of the end of our sample (that is, using estimated state variables and factor dynamics as of July 31, 2023). The simulated factor paths are then converted into forecasts of r_t^* . Figure 15 shows the median projection and the 5th and 95th percentile values for the simulated natural real rate over a ten-year forecast horizon.¹⁹

The median r_t^* projection shows a very gradual reversal of the declines over the past two decades that brings the natural rate back into positive territory by 2032. The upper 95th percentile rises more rapidly and assumes positive values by 2024, while the lower 5th percentile represents outcomes with the natural real rate remaining persistently in negative territory over the entire forecast horizon. Although stationary, these results show that a

¹⁹Note that the lines do not represent short rate paths from a single simulation run over the forecast horizon; instead, they delineate the distribution of all simulation outcomes at a given point in time.

Figure 14: **Comparison with a Macro-Based Estimate of r^***

Illustration of the 5yr5yr expected real short rates, which is equivalent to our definition of r_t^* , implied by our preferred AFNS-L model of Chilean inflation-indexed government bond prices covering the period from August 31, 2003, to July 31, 2023. Also shown is the Chilean macro-based estimate of r_t^* produced by staff at the Central Bank of Chile using the macroeconomic model approach described in Holston et al. (2017). The quarterly data cover the period from 1988Q1 to 2022Q3.

highly persistent model like our preferred AFNS-L model can deviate from the estimated mean for several decades. Thus, nonstationary dynamics such as unit roots or trending shifting end points are not necessary to satisfactorily model the secular persistent decline of interest rates observed in the Chilean inflation-indexed bond market over the past two decades. Of course, like most estimates of persistent dynamics, the model may still suffer from some finite-sample bias in the estimated parameters of its mean-reversion matrix $K^{\mathbb{P}}$, which would imply that it does not exhibit a sufficient amount of persistence—as described in Bauer et al. (2012). In turn, this would suggest (all else being equal) that the outcomes below the median are more likely than a straight read of the simulated probabilities would indicate, and correspondingly those above the median are less likely than indicated. As a consequence, we view the projections in Figure 15 as an upper bound estimate of the true probability distribution of the future path for the natural real rate. Thus, we consider it even more likely that the natural rate in Chile will remain at or near its current new low for the foreseeable future.

Finally, our finance-based estimate of r_t^* appears relevant to the debate about the source of the decline in the equilibrium real rate. In particular, although our measure of the real rate

Figure 15: **Ten-Year Projections of r^* from AFNS-L Model**

Illustration of the 5yr5yr expected real short rates, which is equivalent to our definition of r_t^* , implied by our preferred AFNS-L model of Chilean inflation-indexed government bond prices covering the period from August 31, 2003, to July 31, 2023. Also shown is the 5th percentile, the 50th percentile (the median), and the 95th percentile of ten-year projections of r_t^* based on 10,000 simulated paths drawn from our preferred AFNS-L model.

fluctuated a bit in the immediate aftermath of the financial crisis, our average r_t^* estimate in 2010 is not much different than in 2007 and 2008. This relative stability before and after the financial crisis suggests that flight-to-safety and safety premium explanations of the lower equilibrium real rate are unlikely to be key drivers of the downtrend in Chilean interest rates during this period. Instead, our estimate appears more broadly consistent with many of the explanations that attribute the decline in the natural rate to real-side fundamentals such as changing demographics (e.g., Carvalho et al. 2016, Favero et al. 2016, and Gagnon et al. 2016).²⁰ Moreover, once inflation is brought back under control, our results suggest that real interest rates in Chile—and possibly elsewhere—are likely to return to their pre-pandemic lows, as has also been suggested by Blanchard (2023).

7 Conclusion

Given the historic downward trend in bond yields in the decades before the COVID-19 pandemic, many researchers investigated the factors pushing down the steady-state level of the safe short-term real interest rate. However, because most of this empirical work was

²⁰World Bank data show that the fertility rate in Chile dropped below 2 births per woman in the early 2000s and has been steadily declining since then reaching 1.54 by 2021.

based on *macroeconomic* models and data, uncertainty about the correct macroeconomic specification—in particular during the COVID-19 pandemic shock—has led some to question the resulting macro-based estimates of the natural rate. We avoid this debate by focusing on a finance-based measure of the equilibrium real rate that is based on an empirical dynamic term structure model estimated solely on the prices of inflation-indexed bonds. By adjusting for both inflation-indexed bond liquidity premia and real term premia, we uncover investors’ expectations for the underlying frictionless real short rate for the five-year period starting five years ahead. This measure of the natural rate of interest exhibits a gradual decline over the two decades leading up to the pandemic that accounts for about half of the general decline in Chilean government bond yields. Specifically, as of the end of July 2023, the AFNS-L model estimate of r_t^* in Chile is -1.30 percent with a decline greater than 2 percentage points since the beginning of the 2000s. Importantly, projections of this measure of r_t^* show only a very gradual reversal over the coming decade. This suggests that Chilean—and possibly global—long-term interest rates are likely to return to their pre-pandemic lows once inflation is brought back under control, an issue of immense importance to both fiscal policy and long-term asset management.

As for the liquidity premia of Chilean inflation-indexed bonds, we find them to be large and time varying, as conjectured by the structural arguments in Cardozo and Christensen (2024). Furthermore, regression analysis suggests that it is positively correlated with the concentration of the amount held by buy-and-hold investors as proxied by pension fund holdings and decreasing in the supply of indexed bonds. These results point to large structural frictions in the market for these bonds of the kind described in Cardozo and Christensen (2024), and they underscore the importance of the liquidity adjustment for our analysis. Finally, our regression results suggest that the sizable liquidity premia in the Chilean inflation-indexed bond market are to some extent a function of the fact that about 70 percent of the stock of BTUs is held by pension funds. This raises the question whether our findings are representative and would extend to other emerging bond markets where institutional investor ownership shares may be different. However, we leave this important question for future research.

Given that our measure of the natural rate of interest is based on the forward-looking information priced into the active Chilean inflation-indexed bond market and can be updated at daily frequency, it could serve as an important input for real-time monetary policy analysis and general financial market monitoring. For future research, our methods could also be expanded along an international dimension. With a significant degree of capital mobility, the natural real rate will depend on global saving and investment, so the joint modeling of inflation-indexed bonds in several countries could be informative (see HLW for an international discussion of the natural rate). Finally, our measure could be incorporated into an expanded joint macroeconomic and finance analysis—particularly with an eye towards further

understanding the determinants of any post-pandemic new normal for interest rates.

Table 2: **Sample of Chilean Inflation-Indexed Bonds Cont.**

The table reports the characteristics, first issuance date and amount, and total amount issued in billions of Chilean pesos either at maturity or as of July 31, 2023, for the sample of Chilean inflation-indexed bonds. Also reported are the number of monthly observation dates for each bond during the sample period from August 31, 2003, to July 31, 2023.

B Inflation-Indexed Bond Liquidity Premium Regressions

In this appendix, we provide the full details and results of the regression analysis summarized in Section 5.3 in the main text. Up front we note that throughout the dependent variable in the regressions is the average estimated inflation-indexed bond liquidity premium shown in Figure 6 in the main text.

As explained in Section 5.3 in the main text, our first key explanatory variable is the pension fund share defined as Chilean pension fund holdings of inflation-indexed bonds divided by the total outstanding amount of inflation-indexed bonds. We consider this a proxy for the holdings of all domestic buy-and-hold investors in Chile.

Our second key explanatory variable is the size of the inflation-indexed bond market. Here, our conjecture is that, if the market size increases, the liquidity premia should decline, all else being equal. To test this hypothesis, we use the monthly total outstanding amount of inflation-indexed bonds scaled by nominal GDP.

In Table 3, column (1) reports the result of using these two variables to explain the variation in the average estimated inflation-indexed liquidity premium series. We note that we get a significant positive coefficient on the pension fund share confirming our conjecture and that of Christensen and Cardozo (2024), that is, as the market becomes more dominated by buy-and-hold investors, its steady state moves towards one of increasing liquidity premia. At the same time, we get a significant negative coefficient on the indexed BTU market-to-GDP ratio. This means that an expansion of the inflation-indexed bond market relative to GDP tends to put downward pressure on inflation-indexed bond liquidity premia—a positive effect of increased supply. Hence, positive effects from an expansion of the market relative to the size of the economy may be offset provided the extra bond volume is acquired by domestic buy-and-hold investors.

To verify the robustness of these findings, we next consider several groups of control variables.

To begin, we are interested in the role of factors that are believed to matter for inflation-indexed bond market liquidity specifically. First, we use the average bid-ask spread in the inflation-indexed bond market shown in Figure 4 in the main text. Second, we add the average inflation-indexed bond age and the one-month realized volatility of the ten-year inflation-indexed bond yield as additional proxies for bond liquidity following the work of Houweling et al. (2005). Inspired by the analysis of Hu et al. (2013), we also include a noise measure of the bond prices to control for variation in the amount of arbitrage capital available in

this market. Lastly, we include the inflation-indexed bond market turnover measured as the monthly inflation-indexed bond transaction volume divided by the total outstanding amount of inflation-indexed bonds. Collectively these five variables constitute the liquidity controls referred to in the main text. Adding these five control variables tied to bond market liquidity and functioning to the baseline regression produces the results reported in column (2) in Table 3. We note an increase in the adjusted R^2 to 0.32. However, the control variables are all insignificant except for the average bond age variable, while our two key explanatory variables preserve their statistically significant coefficients, even though they are somewhat smaller in size.

After having explored the role of liquidity factors, we examine the effects of factors reflecting risk sentiment domestically and globally on the inflation-indexed liquidity premium series. This set of variables includes the VIX, which represents near-term uncertainty about the general stock market as reflected in options on the Standard & Poor's 500 stock price index and is widely used as a gauge of investor fear and risk aversion. We also control for a measure of financial frictions in the U.S. Treasury market, the so-called on-the-run (OTR) premium, which captures the difference between seasoned (off-the-run) U.S. Treasury securities and the most recently issued (on-the-run) U.S. Treasury security of the same 10-year maturity. To control for factors that affect emerging market sovereign bonds more broadly, we include the J.P. Morgan Emerging Market Bond Index (EMBI). As an additional indicator of credit risk and credit risk sentiment, we use the five-year credit default swap (CDS) rate for Chile. This set also includes the MOVE index, which is a representative measure of the implied volatility in the U.S. Treasury market and hence serves as a proxy for the risk of fixed-income investments broadly defined. Collectively these five variables constitute the risk sentiment controls referred to in the main text. The result of the regression with these five control variables added to our baseline specification is reported in column (3) in Table 3. We note an increase in the adjusted R^2 to 0.38. Still, only the OTR premium and MOVE have a significant coefficient, and the former even has a negative sign. More importantly, our two key explanatory variables preserve their significant coefficients as in the original regression.

In the final group, we assess the role played by standard macro variables for the inflation-indexed liquidity risk premium series. First, to capture inflation risk in a direct way, we include the year-over-year change in the Chilean CPI. Second, we consider the role of political uncertainty by including a measure of economic policy uncertainty (EPU) in Chile.¹ Next,

Table 3: **Regression Results for the Average Estimated Inflation-Indexed Bond Liquidity Premium**

The table reports the results of regressions with the average estimated inflation-indexed bond liquidity risk premium as the dependent variable and 16 explanatory variables. Standard errors computed by the Newey-West estimator (with three lags) are reported in parentheses. Asterisks *, ** and *** indicate significance at the 10 percent, 5 percent and 1 percent levels, respectively.

we include the Chilean monetary policy rate. In addition to capturing the stance of monetary policy, this rate may serve as a proxy for the opportunity cost of holding money and the

associated liquidity convenience premia of inflation-indexed bonds, as explained in Nagel (2016). The final variable in this set is a measure of relative prices of traded goods for the Chilean economy, which are proxied by the log ratio of copper prices over the West Texas Intermediate (WTI) Cushing crude oil price. Collectively these four variables constitute the domestic macro controls referred to in the main text. The result of the regression with these four standard macroeconomic control variables added to our baseline regression model is reported in column (4) in Table 3. It produces a high adjusted R^2 of 0.45. However, none of the macroeconomic variables are statistically significant. Still, our two key explanatory variables remain statistically significant.

Finally, to assess the robustness of the results from the first four regressions, we include all variables with the results reported in column (5) in Table 3. Although this full joint regression produces a high adjusted R^2 of 0.49, none of the control variables are statistically significant at the 5 percent level. More importantly, our two key explanatory variables remain statistically significant and preserve both their sign and approximate magnitudes as in the earlier regressions. As a consequence, we consider our findings from the regression analysis to be very robust.
