

Interpreting Procyclical Productivity: Evidence from a Cross-Nation Cross-Industry Panel

J. Bradford De Long
and Robert J. Waldmann

De Long is at U.C. Berkeley, the National Bureau of Economic Research, and the Federal Reserve Bank of San Francisco; Waldmann is at the European University Institute.

The authors would like to thank Hoang Quan Vu for research assistance, the European University Institute and the National Science Foundation for research support, and Olivier Blanchard, Susanto Basu, Ricardo Caballero, Tim Cogley, John Fernald, Richard Freeman, Lars Jonung, Richard Lyons, Glenn Rudebusch, Alan Stockman, Larry Summers, and especially Larry Katz for helpful and interesting discussions.

We use an international panel data set of value added by industry to see if labor productivity is procyclical in response to demand shocks. It is: holding fixed our proxy for supply-side factors—the value added levels of an industry in other nations—industry-level productivity rises when value added in the rest of manufacturing rises.

Moreover, increases in unemployment are associated with a lowered degree of procyclicality in the U.S. and with heightened procyclicality in Europe. This suggests that procyclical productivity arises primarily from “labor hoarding” by firms in the U.S. that wish to avoid future training costs and primarily from “job hoarding” by workers in Europe who wish to avoid unemployment.

Labor productivity is procyclical, rising in business expansions and falling in recessions.¹ Some believe that procyclical productivity is ingrained in the technology of production. But a standard view of procyclical productivity sees it as a consequence, not a cause, of changes in activity. Labor productivity falls when output falls because firms retain more workers than required to produce low current output. They do this to avoid the costs of laying workers off now and hiring replacements in the future when activity recovers.² Procyclical productivity does not cause but results from business cycles because firms “value the match” that they have made with their employees.³

This account has been challenged by real business cycle theories which speculate that the shocks driving the business cycle are not shocks to demand, but are instead technology-driven shocks to productivity in particular industries (for example, Kydland and Prescott 1982; Long and Plosser 1983). Such industry-specific technology shocks directly cause an increase in production in the affected industry. They cause increased production in other industries by (i) increasing the wealth of consumers, (ii) increasing demand for intermediate inputs used in the directly affected industry, and (iii) increasing demand for (gross) complements of the output of the directly affected industry.⁴

Such theories have been criticized on the grounds that they cannot account for correlations in *productivity* (Summers 1986) though they might account for correlations in *output* across industries. Demand spillovers from positive technology shocks in one industry should lead to reduced labor productivity in other industries.⁵ But production and

2. See Holt, et al. (1960), Oi (1962), and Okun (1962).

3. This literature is reviewed by Fair (1969), Hamermesh (1976), and Nickell (1986). See also Aizcorbe (1992), Rotemberg and Summers (1988), Summers and Wadhvani (1988), and Medoff (1979).

4. There are also views in which procyclical productivity is both cause and effect, and multiple equilibria are possible. See Benhabib and Farmer (1996), or Murphy, Shleifer, and Vishny (1989).

5. Under the assumption that the short-run marginal product of labor is decreasing.

productivity are positively correlated across industries. Some have made the assumption that supply-side shocks are industry-specific, while demand shocks are aggregate. They have regressed productivity in an industry on total productivity or production to show that demand shifts—not shifts in supply—underlie procyclical productivity.⁶

This, however, is not a convincing refutation of supply-side theories. There are supply-side shocks that affect labor productivity in many industries at once: the oil price shocks of 1973 and 1979, for example. Such shocks generate procyclical productivity in many industries: producers shift away from the now-expensive factor of energy and use labor more intensively. A real business cycle-driven response of economies to oil shocks creates aggregate movements in productivity and output. Economists assuming that “supply” is industry-specific and “demand” aggregate would falsely interpret such movements as evidence that procyclical productivity was demand-driven.

This paper attempts to take some steps toward disentangling demand- and supply-driven components of procyclical productivity without making the possibly dangerous assumption that everything aggregate is demand. It uses Alan Stockman’s insight that there are a great many technology and cost shocks—like the oil shocks of 1973 and 1979—that directly affect productivity in many *industries* and also affect productivity in many *nations*. A cross-industry cross-nation panel of data on value added by industry can be used to separate the effects of demand and supply shocks if supply shocks are truly “technological”—that is, they affect the production process no matter where in the world it happens to be located.⁷

Industrial value added shifts correlated with value added shifts in other industries in the same economy, and yet not correlated with industrial value added shifts in other nations, are candidates for the label “demand.” How could a change in an industry’s *technology* of production affect other industries in the same country but not the same industry in other countries? Industrial value added shifts correlated with value added shifts in the same industry in other nations, but not correlated with value added shifts in other industries in the same country, are candidates for the label “supply.”

The effects of idiosyncratic national aggregate demand shocks can be determined because such shocks are both intersectoral and nation-specific.

6. See Hall (1986); Domowitz, Hubbard, and Petersen (1988); Caballero and Lyons (1990 and 1992); and Shapiro (1987). These studies place the measured Solow residual on the left hand side of their equations, while we focus on labor productivity.

7. See Stockman (1988).

Needless to say, we do not believe that “supply” shifts caused by technology or even changes in prices diffuse instantly across the nations of our sample. However, we do believe that such shifts ought to spread over the countries in our sample within a few years. And it is certainly important to control for such supply shifts before concluding that procyclical productivity is demand-driven.

We are concerned that much of the evidence on procyclical productivity is driven by relatively low-frequency changes in productivity and output growth—which was high in the 1960s, low during a period from the early 1970s to the early 1980s, and moderate through the later 1980s. Such low-frequency changes might well be supply-driven, rather than demand-driven. We do not believe that supply-side effects will be adequately removed by using instruments, for example U.S. military spending, that while not causally related to supply factors nevertheless have much of their own variance produced by low-frequency movements.

The identifying assumptions we require are relatively minor. One need not assume that technological progress is uniform across countries. One need only assume that there are no technological or other supply-side shocks that are (a) specific to a single country, yet (b) affect a broad range of industries within manufacturing.⁸

We find that even after controlling for industry-specific cross-nation shocks, sectoral productivity growth remains positively correlated with aggregate manufacturing output. This suggests that increased aggregate demand does lead to increased labor productivity, and that there is a component of procyclical productivity that could be accounted for by an old-fashioned Keynesian “labor hoarding” story, or by some other model in which firms and workers value their match.

We go on to investigate the cross-nation pattern of procyclical productivity. If firm-side labor hoarding—due to workforce finding and training costs—is important, productivity should be more procyclical when unemployment is low.⁹ When unemployment is high, laid off workers are less likely to find new jobs and are more likely to be avail-

8. We use labor productivity and not total factor productivity as a dependent variable, and so our results on procyclical productivity cannot be attributed to market power. Our calculations are not affected by deviations of prices from marginal products.

9. In the United States, labor productivity appears less procyclical in highly unionized industries (see Medoff, 1979; Freeman and Medoff, 1984). This might arise because unionized workers share rents, would be likely to suffer a cut in wages if they took jobs in non-union establishments, and so wait to be around. Thus the firm is free to lay them off temporarily when demand is momentarily slack without risking the loss of the value of the match.

able when the firm wishes to recall them, so the incentives for the firm to engage in labor hoarding are diminished.

If worker-side job hoarding—firing costs that firms bear when workers are laid off but avoid when workers voluntarily quit—is important, then productivity should be more procyclical when unemployment is high: workers will then resist dismissals with more determination, quits will be rare, and restrictions on layoffs may bind more when unemployment is high.¹⁰

If procyclical labor productivity is simply a consequence of increasing returns to scale, as in Caballero and Lyons (1990 and 1992) or many others, the procyclicality of production should be unaffected by the level of the unemployment rate.

We find that in the United States labor productivity is less procyclical when unemployment is high. In Germany and—less strongly—in Britain and in Europe as a whole, however, there is some weak evidence that productivity is more procyclical when unemployment is high. There are differences between the U.S. and Europe in sign and strength of the relation between the degree of procyclicality in productivity and unemployment.

This difference suggests that demand-driven procyclical productivity may spring more from labor hoarding in the United States and more from job hoarding in Europe.¹¹ The dependence of the cyclical behavior of productivity in these nations on labor market conditions raises the possibility that procyclical productivity arises from national institutions that mold the dynamic relationships between workers and firms and is not simply the result of an increasing returns to scale technology.

After this introductory section, Section I describes the data used in this paper. Section II presents the evidence on the existence of procyclical productivity in response to demand shocks. Section III correlates the degree of procyclical productivity with the unemployment rate. It leads to the tentative conclusion that “worker hoarding” by firms

is relatively more important as a cause of procyclical productivity in response to demand shocks in the United States, while “job hoarding” by workers is relatively more important as a cause of procyclical productivity in response to demand shocks in Germany and perhaps in Britain. Section IV concludes.

I. AN INTERNATIONAL INTERSECTORAL PANEL OF VALUE ADDED BY INDUSTRY

We use the OECD International Sectoral Data Bank as our primary data source (Meyer-zu-Schlochtern, 1988). Our data set contains annual data on real value added, employment, and capital by industry for fourteen OECD nations. Since our approach requires a balanced panel and we strongly desire sample of long length, we are forced to focus on seven nations for which data on real value added are available from the 1960s onward—Belgium, Finland, France, Germany, Norway, the United Kingdom, and the United States.¹² Data are available for seven ISIC industries within the manufacturing sector: food, textiles, paper, chemicals, non-metallic minerals (i.e., stone, clay, and glass), basic metal production, and mechanical equipment. Observations are available from 1966 to 1987.

Unfortunately, changes in data collection and definition keep us from extending our sample beyond 1987 while still retaining data from the late 1960s and early 1970s: we have chosen to maximize our sample length.¹³

The OECD international sectoral database includes employment by industry, but it does not include average hours worked by industry. We augment the data by multiplying employment by average hours worked in manufacturing.¹⁴ This procedure assumes a perfect correlation between average hours worked in different industries. Thus it induces positively correlated measurement error between total hours worked in different industries.

Since hours are correlated with value added, this measurement error induces a negative correlation between value added per man-hour in one industry and in another. The

10. See Blanchard and Summers (1986), Bentolila and Bertola (1990), and Krugman (1988).

11. Abraham and Houseman (1989) use a panel of ten matched U.S. and German manufacturing industries, and find that the immediate effect of a reduction in shipments on employment is much smaller than Germany. They interpret their findings as implying that German firms, because of worker job hoarding, are less free in the short run to use layoffs to adjust unemployment. They also find that the workforce adjustment process was slower in Germany after 1972. In 1972 German legal restrictions on layoffs were significantly strengthened by the Works Constitution Act, and the post-1972 period has seen higher unemployment. Abraham and Houseman, however, are unable to control for changes in technology and costs—particularly the cost of oil—and are forced to assume that production is exogenous. Our broader panel of countries should make it possible to control for such factors to some degree.

12. Netherlands data are also available for the 1960s. Unfortunately a change in definitions in 1970 makes Dutch data from the 1960s incomparable to data from 1970 on.

13. We have experimented with alternative data definitions that omit the first years of our sample and contain more recent observations. The statistical results we obtain are very similar with one notable exception: the United Kingdom’s pattern of procyclical productivity is closer to that of the United States and further from that of the rest of Europe the more recent the data. We speculate that this reflects changes in the British economy as a result of Prime Minister Margaret Thatcher’s attempts in the 1980s to curb the power of British unions and make the British labor market more “competitive.”

14. Unpublished data were kindly provided by Robert Gordon.

use of average hours in manufacturing, instead of average hours in each industry, biases the data against revealing procyclical labor productivity.¹⁵

We do not possess data on average hours worked in Finland. Reported average hours worked can be found in the I.L.O.'s *Labor Statistics Yearbook*, but reported average hours from this source show a large increase, from 38.5 hours per week in 1978 to 41 hours per week in 1979. This shift is large relative to other variations, and we believe it reflects a change in coverage. Finland, therefore, was excluded from all regressions that required average hours worked.

In addition, data on employment in basic metals and in equipment are not available for France or Belgium in the 1960s. Regressions using these industries as dependent variables therefore use data since 1970 only.

II. PROCYCLICAL PRODUCTIVITY AND AGGREGATE DEMAND

Nation-Specific Aggregate Demand Movements

It is fruitless to try to use nation-specific movements in manufacturing value added to identify demand-driven movements in productivity unless such movements exist. Stockman (1988) has already used an international intersectoral panel to identify demand-specific and supply-specific movements in output. Stockman assumed that all industries have the same cyclical responsiveness to shifts in aggregate demand—that, in the language of finance, all have the same β_i with respect to aggregate output—and that all countries have the same β_i responsiveness to international supply shocks.¹⁶ In spite of these restrictive assumptions on the form of his nation- and industry-specific components, Stockman found that 12.2% of variance of industry value added is accounted for by nation-specific components that are orthogonal to industry-specific value

15. An additional data problem is posed by the fact that labor productivity data are not available whenever value added data are available. Oddly, the OECD does not report total manufacturing employment in the U.S. before 1968. The ISIC classifications used by the OECD do not correspond exactly to SIC classifications, and so comparable data cannot be added from BLS sources. The OECD does, however, provide data on wage and salary employment in U.S. industries for the 1960s. Fitted values from a regression of total employment on wage and salary employment were therefore used as a proxy for total employment. The R^2 of these regressions ranges from 99.5% to 99.9%. We conclude that it is unlikely that this neglect of the self-employed induces significant biases.

16. Another possibly dubious assumption. For example, the U.S. imposed oil price controls after the 1973 oil shock, and so the real price of oil in the U.S. did not rise as much as in other nations. We would be surprised if substitution away from intensive use of energy proceeded as fast in the U.S. as in Europe after 1973.

added movements, and that 14% of variance is accounted for by industry-specific components orthogonal to nation-specific output movements.

Waldmann (1991), using the OECD database, estimated nation and industry effects without imposing the assumption that β_i and γ_i coefficients were constant across industries. He found that orthogonal nation effects account for 17% of the variance in real value added, while orthogonal industry effects account for only 9.5% of the variance. He also found that orthogonal nation effects accounted for a very small fraction of the variance in real value added in small open economies such as Belgium and Finland; this is reassuring, because standard open-economy models suggest that countries like Belgium and Finland should not have a significant nation-specific business cycle. Results from Waldmann (1991) are reproduced as Table 1.

The divergence of the strength of nation-specific movements in manufacturing value added leads us to anticipate that our attempts to identify demand-driven procyclical productivity will have almost no power in small open economies like Belgium, Finland, and Norway. The existence of large nation-specific components in value added for larger countries leads us to anticipate that our procedures will have considerable power for large countries—the polar case of the United States, and also France, Germany, and the United Kingdom—where spillovers of demand shocks are smaller, and where there appears to be more of a nation-specific business cycle.¹⁷

Initial Regressions

The growth of value added per man-hour for industry i in nation n was regressed on the growth of value added of the rest of manufacturing in nation n , and on the average growth of production per man-hour in industry i in other countries, as described in equation 1:

$$(1) \quad \{\log(Y/N_{int})\} = c_{ni} + \beta_{ni}[\{\log(Y_{nt} - Y_{int})\}] \\ + \gamma_{ni}[\{\log(Y/N_{i(-n)t})\}] + \epsilon_{int},$$

17. It would not be appropriate to draw the conclusion that aggregate demand shocks account for twice as much of the variance in the typical industry's value added growth rate as supply shocks. Undoubtedly, most of both supply- and demand-side shocks are left unidentified by our procedures. We wish only to maintain that the 17% of industry value added growth rate variance that is (a) correlated with changes in the rest of manufacturing production in the same country while (b) orthogonal to changes in value added in the same industry in other countries is not supply. (Conversely, the 9.5% of industry value added growth rate variance that is (c) correlated with changes in value added in the same industry in other countries but (d) orthogonal to changes in the rest of manufacturing production in the same country is not demand.)

where Y/N denotes value added per man-hour; subscripts i , n , and t run over industries, nations, and years, respectively; Y_{nt} refers to value added in all of manufacturing in country n in year t ; $Y_{nt} - Y_{int}$ denotes value added in manufacturing in country n in year t in all industries except industry i ; and a subscript $(-n)$ denote averages over the other countries in the sample (i.e., excluding country n) for an industry i . Results from estimating equation 1 are reported in Tables 2 through 4.

Table 2 reports the β coefficients, which measure the sensitivity of industry-level value added per man hour to movements in value added in the rest of manufacturing in the same nation (holding constant value added in that particular industry in other nations). The β coefficients on the growth of manufacturing are generally positive. The precision-weighted average is positive for all nations. The precision-weighted average across countries of β coefficients for a given industry vary strikingly.

Under the assumption that the disturbance terms for different industries are independent, standard errors for the precision-weighted averages within industries and within nations of the β coefficients were calculated and are reported in Table 2. However, this assumption is not valid. Instead, seemingly-unrelated-regressions procedures were

used to test the null hypothesis that labor productivity is not procyclical when controlling for value added growth in the same industry in other countries. Data on different industries were stacked, and equation 1 was reestimated with the β coefficient restricted to be the same in different industries.¹⁸

Table 2 also reports seemingly-unrelated-regressions estimated coefficients on the growth of the rest of manufacturing in the same country. The coefficients are all positive and are similar to the precision-weighted national average OLS estimated β coefficients. Their rank order is almost unchanged. All coefficients, save that of France, are within one standard error of the precision-weighted national average coefficients. The reported standard errors are somewhat larger for the SUR estimates.¹⁹

18. Unfortunately, when seemingly-unrelated-regressions procedures are used and international averages are included, the sample contains only those years in which all industries in all countries report data. The absence of data from the 1960s on employment in the basic metals and metal equipment industries in France and Belgium leaves only five industries in six countries.

19. Since the true standard errors must be smaller, this implies that the reported standard errors of the weighted averages are understated.

NOTES: Standard errors in parentheses.

Regressions control for average productivity growth in the same industry in other countries.

^aEquation for five industries estimated by SUR, restricting β to be the same in each industry. Regression does not use data from basic metals or mechanical equipment.

The disturbances in different countries are nearly orthogonal by construction, because international averages of productivity growth in the same industry in the other countries are included in the regressions. Therefore, a standard error can be calculated for the grand precision-weighted average of the SUR coefficients estimated for each nation. The grand precision-weighted average is 0.127, with a standard error of 0.033. Labor productivity thus remains procyclical after controlling for the average rates of industry productivity growth in different countries.

Table 3 reports the estimated coefficients, which capture the responsiveness of productivity growth in an industry to value added growth in the same industry in other

countries (holding constant value added in the rest of the manufacturing sector of that particular country). The industries that appear most sensitive to "supply" conditions, as captured by the growth of value added in the same industry in other countries, are the chemicals and the non-metallic minerals industries. The industries that appear least sensitive are the food products and textiles industries.

Table 4 shows that the fraction of the variance in productivity accounted for by orthogonal nation-specific effects is much smaller than the fraction of the variance in value added explained by orthogonal nation-specific effects in Table 1. Orthogonal nation-specific effects account for 4.98% of the variance, including the variance "explained"

for industries which have negative estimated coefficients on value added in other industries. In each country, it is far lower than the partial R^2 for the regressions in Waldmann (1991), with value added as the dependent variable.

Table 4 also shows that the fraction of total variance in value added per man-hour explained by orthogonal industry effects is on the order of one-tenth, somewhat higher than the fraction of the variance of value added accounted for by orthogonal industry effects in Waldmann (1991). Since employment in different industries is highly correlated, this finding that the nation effects on labor productivity are smaller than nation effects on value added is not unexpected.

Omitted Variable Bias

The presence of significant nation effects on labor productivity would appear to be evidence in favor of labor hoarding-based, job hoarding-based, or increasing returns to scale-based interpretations of procyclical labor productivity. Increased aggregate demand causes increased labor productivity, even controlling for cost and supply shocks.

But before the orthogonal nation-specific effects can be interpreted as effects of aggregate demand, at least some attempts to control further for supply shocks would be desirable. We examined three possible sets of omitted supply-side variables.

The first avenue of approach was that perhaps the rate of productivity growth in the nations of the sample shifts over time. A linear trend was added to the regressions which—since the dependent variable is a growth rate—corresponds to allowing for quadratic trend in the level of productivity. Such a trend has almost no effect on the estimated coefficients on national value added in the rest of manufacturing. For example, the seemingly-unrelated-regressions estimated coefficient for the United States is 0.032 instead of 0.037, and the summary precision-weighted average of the coefficients on national manufacturing remains 0.127 (results not shown).

The second avenue was to try to control explicitly for the oil shocks of the 1970s. Controlling for average productivity growth in the same industry in different countries is to some degree a control for the effects of the oil shocks of the 1970s. But oil shocks may well have had different

effects on different nations—on oil exporters such as England and Norway, for example.

Since the complex pattern of effects of the oil shocks on an industry may not have been captured by a single coefficient, we reestimated the productivity regressions including as additional explanatory variables the change and the lagged change in the price of oil. Once again, the additional regressors had little effect on the estimated coefficients. The summary precision-weighted average of the seemingly-unrelated-regressions coefficients on national value added in the rest of manufacturing increases from 0.127 to 0.128 (results not shown).

The third avenue considered was to include estimates of the capital stock in order to examine the procyclicality not of labor productivity but of total factor productivity—the Solow residual. Up to this point the Solow residual has been neglected for three reasons. First, the data set does not contain adequate data on shares of labor and capital in

pre-tax value added; second, OECD studies based on the data warn that reported factor shares are unreliable (see Meyer-zu-Schlochtern, 1988).²⁰ Third, Solow residuals exhibit spurious cyclicity if firms possess market power (Hall, 1986 and 1988).²¹

To investigate whether the omission of capital stock variables was biasing our results, we assumed that the elasticity of value added with respect to labor and capital was constant and imposed constant returns to scale to arrive at

20. In fact, such studies throw away the reported factor share data and instead arbitrarily assume that the share of labor is 75%.

21. A corrected Solow residual could be constructed under the assumption that the ratio of price to marginal cost is constant, but there is little reason to believe this assumption (see Domowitz, Hubbard, and Petersen, 1988).

a Cobb-Douglas production function in which value added per man-hour is a function also of the capital/labor ratio.²² This led to equation 2:

$$(2) \quad \{\log(Y/N_{int})\} = c_{ni} + \alpha_{ni} [\{\log(Y_{nt} - Y_{int})\}] \\ + \beta_{ni} [\{\log(Y/N_{i(-n)t})\}] \\ + \gamma_{ni} [\{\log(K_{int}/E_{int})\}] + \delta_{int}$$

where K stands for the real capital stock and E for the level of employment.²³

22. Data on capital stocks are not available for Finland. However, the absence of reliable average hours data for Finland makes its inclusion impossible in any event. Data on capital stocks in Norway in the 1960s also do not exist in the data set, reducing the number of countries in the sample to five.

23. The ratio of capital per worker, rather than the ratio of capital per man-hour, is used on the assumption that the work week of capital is the

The results of regressions including the capital/labor ratio were disappointing. Summary α , β , and γ coefficients for nations and industries are reported in Table 5. The estimated coefficients on the capital/labor ratio are often implausible: for 13 of 35 underlying regressions, the coefficient on the capital/labor ratio is negative. The precision-weighted average coefficient is negative for France; for England the average coefficient is enormous and implausible.

We ascribe these disappointing results to the fact that the variance of changes in capital stocks is low, and so changes in the capital/labor ratio are nearly the negative

same as work week of workers. Under the alternative assumption that the work week of capital is fixed, and thus that the appropriate capital/labor ratio is capital divided by hours worked, the estimated elasticity of value added with respect to capital is negative for most industries and most countries.

NOTES: Standard errors in parentheses.

Regressions control for average productivity growth in the same industry in other countries.

of changes in employment.²⁴ This interpretation is supported by the finding of similar results when the capital/labor ratio is replaced by 1/employment (results not shown): the coefficients on 1/employment are in fact greater than the coefficients on the capital labor ratio. We conclude that the OECD estimates of capital are not useful in attempting to analyze labor productivity over the 1960s, 1970s, and 1980s.²⁵

Each of the different sets of regressions that we have run is vulnerable to criticism based on the omission of a potential supply side effect. The similarity of results that devote different degrees of effort to controlling for such effects in the specifications we have tried, together with the finding that all regressions show significant nation effects, suggest that these criticisms may not be crippling.

The inclusion of valid supply-side variables should reduce estimated nation effects even if the supply-side variables are relatively poor proxies for the true underlying determinants of procyclical productivity. This does not take place. Thus we are more confident that the estimated association of value added and productivity shows that increased demand leads to increased labor productivity.

Instrumental Variables Estimates of Procyclical Labor Productivity

An appropriate measure of the magnitude of demand-driven productivity changes in a given industry is the elasticity of hours worked with respect to value added. In Table 6, we estimate this elasticity by instrumenting the demand for each industry's value added by the growth of manufacturing value added in the same country outside that industry. The estimates reflect not only long run elasticities of hours

24. In this case, the large coefficient estimated for England perhaps reflects the fact that the capital/labor ratio is picking up the large negative disturbance to employment following the accession of Margaret Thatcher (Layard and Nickell, 1989). There was a large drop in English manufacturing employment in 1982. This huge drop in employment corresponds to a huge increase in the measured capital/labor ratio and to a huge increase in production per man-hour. Such an increase can be interpreted as showing that employment follows value added with a lag due to job hoarding, or that by 1983 Thatcher had finally terrorized the unions enough that she and private firms could fire workers in droves (see Bertola and Bentolila, 1987). Neither explanation has anything to do with the effect the capital/labor ratio is supposed to capture—that workers can produce more value added working with machines than without them.

25. It is reassuring to note that the inclusion of the capital/labor ratio does not change the measured cyclicity of labor productivity enormously. Labor productivity remains procyclical controlling for growth in the same industry in other countries when the capital/labor or the 1/employment ratios are included in the regressions.

with respect to value added, but also the effects of labor or job hoarding, which should reduce the elasticity of hours worked with respect to value added.

In Table 6 no additional regressors are included to control for industry-specific shocks. The precision-weighted average of the estimated elasticities are all near one-half. Even for Germany, the nation with the highest value, the precision-weighted average coefficient is significantly less than one—implying that labor productivity is procyclical. The U.S. has the second highest average elasticity, noticeably greater than the elasticity estimated for any European country save Germany. The fact that total hours adjust the same amount in the United States and Germany confirms the results of Abraham and Houseman (1989).²⁶

Table 7 adds the average change in value added and in hours worked in the same industry in other countries as additional regressors to control for supply shocks. With these variables included, estimated elasticities differ more across countries: removing averages highlights national differences. All precision-weighted national averages of elasticities are significantly less than one. Germany continues to exhibit the highest average estimated elasticity, with the lowest for Belgium. Such elasticities also suggest that labor productivity is procyclical after controlling for cross-national supply shocks.

Table 8 reports national average coefficients from instrumental variables regressions of the elasticity not of man-hours but of employment with respect to value added, controlling for average growth of employment and value added in the same industry in other countries.²⁷ The U.S. has a markedly greater precision-weighted average estimated elasticity than most European countries. For five of the six European countries the estimate is on the order of 0.3 or smaller: Finland is the exception.²⁸

This is of interest: labor and job hoarding work to prevent layoffs, not necessarily to keep hours unchanged. The differing elasticities suggest that there may be some returns to pursuing institution-based explanations of procyclical productivity. The next section correlates the degree

26. The much lower elasticities estimated for European countries other than Germany suggest that, as Abraham and Houseman note, their results may have been caused in part by the fact that Germany reports hours actually worked, while other countries instead report hours paid.

27. Results are similar without the controls.

28. One possible problem with this result is that changes in average hours worked reflect not only the adjustment of hours worked by normally full-time workers, but also changes in the proportion of full- and part-time workers. The result may simply show that in the U.S. part-time work is more cyclical than in Europe, so average hours worked are less cyclical.

of procyclical productivity with unemployment. It argues that procyclical productivity is driven by institutional interactions of workers and firms, and not by technological interactions of workers and machines.

III. PROCYCLICAL PRODUCTIVITY AND THE UNEMPLOYMENT RATE

The previous section establishes a presumption that a component of procyclical productivity is independent of supply-side shocks and is, instead, a consequence of shifts in demand. There are at least three interpretations of how such demand-driven procyclical productivity comes about. First, there may be increasing returns. Second, firms may hoard labor. Third, workers may hoard jobs.

Each interpretation leads to its own predictions of the likely cross-country pattern of procyclical productivity, and of the shifts over time in the cyclicity of productivity. "Job hoarding" by workers is likely to show itself most

clearly in European countries, which have stronger labor movements and job protection legislation than the United States (see Cross, 1985; Bentolila and Bertola, 1990; Clarke, 1988; and Lazear, 1990).

Section II noted that the U.S. shows more adjustment of employment to shifts in demand than does Europe. It is difficult to see how increasing returns could produce such a pattern: European industry would have to have more sharply increasing returns than U.S. industry. It seems more straightforward to conclude that the European labor market has institutions that cause more labor hoarding, or job hoarding, than those of the United States.

The cross-country pattern alone does not tell us whether procyclical productivity arises because of hiring costs—firms hoarding workers because they fear they will not find personnel when the economy recovers—or because of firing costs—workers hoarding jobs because their positions in the labor market are valuable assets in which they have quasi-property rights.

Distinguishing between Labor Hoarding and Job Hoarding

More information on the relative importance of labor hoarding, job hoarding, and increasing returns can be gained by looking at shifts in the cyclical productivity within each country. Increasing returns suggests no link between procyclical productivity and macroeconomic variables. But if labor hoarding is the cause of procyclical productivity, then productivity will be less cyclical in periods of high unemployment. In a time of high unemployment firms need not fear that workers will find new jobs and be unavailable when business picks up. Firms are therefore more likely to use temporary layoffs to manage their costs when the unemployment rate is chronically high.

By contrast, if workers resist layoffs—and “hoard” their jobs—because they are well organized or because of employment protection legislation, labor productivity will be more procyclical when unemployment is high. At a low un-

employment rate quits will be sufficient for firms wishing to reduce work forces to do so by attrition. Unions are unlikely to spend political capital resisting layoffs when members can easily find other good jobs.

In the United States, labor productivity is less cyclical in unionized industries (Medoff, 1979; Freeman and Medoff, 1984). This suggests that labor hoarding is more important than job hoarding: if workers resisted layoffs, they would be more able to do so in highly unionized industries. If job hoarding were an important cause of U.S. procyclical productivity, labor productivity would be more cyclical in highly unionized industries. This cross-sectional pattern leads to the prediction that labor productivity will be less procyclical in the U.S. when the unemployment rate is chronically high.

By contrast, high unemployment should increase the procyclical productivity in Europe. In Europe, powerful union movements and legal restrictions on layoffs are likely to make job hoarding important. When unemploy-

ment is high workers are less likely to quit. And workers are more likely to resist layoffs when unemployment is high and makes their jobs valuable property.²⁹

In either case, a significant effect of unemployment on the cyclicity of labor productivity is evidence that hiring and firing costs are among the causes of procyclical productivity. The absence of an effect would be evidence that the cause may be technological change and increasing returns.

29. Just as anticipated future hiring costs may prevent layoffs during recessions, anticipated firing costs may reduce hiring during expansions. An extensive literature discusses the possibility that increased unemployment may have caused the constraints on layoffs in Europe to become binding (see Blanchard and Summers, 1986 and 1988; Bertola and Bentolila, 1990; Krugman, 1988; Freeman, 1988). It has been noted that aggregate employment and unemployment fluctuations have become more persistent in Europe in the 1980s (Blanchard and Summers). It is important to learn if this reflects greater persistence in demand fluctuations, or instead a reduced response of employment to demand fluctuations.

Estimating the Effect of Unemployment on the Procyclicity of Productivity

The interaction of value added growth and the unemployment rate was added to the independent variables of equation 1, giving equation 3:

$$(3) \quad \{\log(Y/N_{int})\} = c_{ni} + \alpha_{ni} [\{\log(Y_t - Y_{int})\}] \\ + \beta_{ni} [\{\log(Y/N_{i(-n)t})\}] \\ + \mu [U_{n[t-1]} - \text{Avg}(U_{nt})] \\ [\{\log(Y_t - Y_{int})\}] \\ - \text{Avg}(\{\log(Y_t - Y_{int})\}) + \epsilon_{int},$$

where $U_{n[t-1]}$ is the unemployment rate in nation n lagged $t-1$ years. We estimate equation 3 for α equal to 1 and 2—with value added growth in the rest of manufacturing interacted with unemployment lagged one and two years. We lag unemployment one year to reduce correlations between

this period's disturbance and this period's unemployment rate. We lag unemployment two years for two reasons. First, since all data are averages over a year of continuous-time processes, a two-year lag is needed to purge the correlation of current disturbance terms.

Second, use of unemployment lagged two years serves as a specification check: we believe that the degree of procyclical productivity changes relatively slowly, as workers' and firms' perceptions of the ease of finding new jobs or new workers shifts. If results differed depending on the exact lag of unemployment, we would no longer believe our specification.

In equation 3, averages are taken over 1963–84 for each individual nation. Average unemployment and rates of value added growth in the rest of manufacturing were subtracted in the second line of equation 3 to make the estimates of μ and β comparable to those estimated for equation 1. For each country, the system of equation 3 for the five industries (food, textiles, paper, chemicals, and non-metallic minerals) was estimated by seemingly-unrelated-regressions procedures, restricting μ to be the same across industries.³⁰

30. Similar results were obtained by estimating equation 3 by OLS for these industries, and for basic metals and mechanical equipment, and calculating the precision-weighted national average of the estimates of μ .

For those four nations with data available on employment in metals and equipment in the 1960s, the system was estimated for all seven industries as well, restricting μ to be the same across industries.

The first set of estimated μ interaction coefficients are presented in Table 9. For each country-industry pair, it presents the values of the interaction coefficients from regressions of the growth of value added per hour worked on value added growth in other industries in that nation, the average of value added growth in the same industry in other nations, and the interaction of the unemployment rate level with national value added growth. For the United States the interaction term is negative and significant. This provides some evidence suggesting that labor hoarding is a dominant cause of U.S. procyclical productivity.

For Germany, the interaction is *positive* and significant, suggesting that job hoarding is a predominant cause of procyclical productivity and is more prevalent during periods of chronically high unemployment. For Britain the interaction is positive, but its significance is borderline and changes from specification to specification.

For France and Belgium, the coefficient is negative and insignificant. For Norway, it is far from significant with a huge standard error, and its sign depends on the specification. The failure of a pattern to emerge for the small open economies of Norway and Belgium is not unexpected. The

interaction term is only identified by the orthogonal nation-specific shock to aggregate demand, and these small open economies possess only small nation-specific movements in total manufacturing value added.³¹ The failure of a pattern to emerge for France is disappointing, for France is large and has pursued independent macroeconomic policies over the past third of a century. We expected to see stronger results.

However, the difference between the interaction coefficients estimated for the United States and those estimated for a pooled sample of European countries is large and highly significant. Procylical productivity is weaker in the United States when unemployment is high, but it is not weaker in Europe. It is difficult to argue that the same

“labor hoarding” that appears to generate procyclical productivity in the U.S. generates it in Europe as well.

The dependent variable in equation 3 is production per man-hour. Since hiring and firing costs are likely to depend on the change not in man-hours but in employment, it is interesting to compare the behavior of production per worker with the behavior of production per man-hour.³² Similarity in coefficients would suggest that the results in Table 9 are not simply due to changes in the labor force or differences in the reporting of hours worked.

Equation 3 was thus reestimated, replacing value added per man-hour by value added per worker. Table 10 reports the results, which are indeed similar to those reported in Table 9. The procyclicality of value added per worker undergoes the same shifts with changing unemployment as does the procyclicality of value added per man-hour. The interaction term is significantly negative only for the U.S., for

31. The magnitude, however, of the Norwegian interaction coefficient is deserving of explanation. We tentatively ascribe the high magnitude to the fact that the Norwegian unemployment rate exhibits a very small rise in the 1970s, and is therefore highly collinear with a post-North Sea oil discovery dummy variable. Under this interpretation, the coefficient is capturing the fact that Norwegian productivity became much more sensitive to the level of production in Norway after the discovery of North Sea oil. If this interpretation is correct, the coefficient carries little information about the magnitude of job hoarding in Norway.

32. Ideally, one would want to examine labor hoarding by examining hours worked by workers who normally work full time—thus obtaining a more direct measure of overtime and slack time hours. As noted above, differences between countries in the cyclicity of production per worker can reflect differences in the cyclicity of part time work. Changes over time within a country also reflect, among other things, the entry of women into the labor force.

which it is virtually unchanged. For the European countries the coefficients are somewhat smaller, but still positive.³³

Errors in and Omissions of Variables

Controlling for average productivity growth in the same industry in different countries has the important advantage of controlling for supply shocks. But from a Keynesian standpoint, it would be disturbing if results were substantially changed if the international average growth rates of value added in individual industries were excluded from the list of independent variables. It is also possible that the average of growth in the same industry in other countries is not an appropriate measure of supply and cost shocks: perhaps nation-specific shocks—like the discovery of North Sea oil—contaminate the results for other countries. To the extent that nation-specific industry value added movements reflect the discovery of a nation-specific shock, like the discovery of North Sea oil for Norway, the average across nations of value added growth in an industry is a poor measure of true supply shocks.

These considerations led us to repeat the interaction regressions without controlling for average growth in the same industry in other countries, as shown in equation 4:

$$(4) \quad \{\log(Y/N_{int})\} = c_{ni} + \alpha_{ni} [\{\log(Y_{nt} - Y_{int})\}] \\ + \mu [U_{n[t-1]} - \text{Avg}(U_{nt})] \\ [\{\log(Y_{nt} - Y_{int})\} \\ - \text{Avg}(\{\log(Y_{nt} - Y_{int})\})] + \epsilon_{int}.$$

Except for Norway itself, the interaction terms were virtually unchanged, as Table 11 shows.

Omitted variables might corrupt our results. Productivity might be more cyclical in Germany and Europe when unemployment is high simply because both the unemployment rate and the cyclical of labor productivity have increased for other reasons. It is easy to see how the cyclical of labor productivity could have a positive trend if, say, the ratio of administrative to production workers increases over time. Given the time pattern of European unemployment, the interaction terms in the regressions come close to comparing the cyclical of labor productivity in

the later half of the sample to the cyclical in the earlier half of the sample.

While the use of a disaggregated dependent variable—of sector-specific value added—gives greater precision, it does not increase the ability to discriminate between increased unemployment and the effect of time. In the case of the United States, the time pattern of unemployment makes it correlated with lagged oil shocks; lagged oil shocks might have reduced the cyclical of labor productivity.

In each case it is possible in principle to control for omitted variable bias by including an additional independent variable: the omitted variable interacted with the growth in manufacturing value added. But such regressions are likely to lack power.

We use an alternative procedure. If German unemployment is standing in for an omitted variable, this omitted variable should also have been in operation in other countries. If a secular increase in the amount of overhead labor is making productivity more procyclical, and if the German unemployment rate is correlated with this omitted variable, then a regression of productivity growth in an *American* industry on the growth of value added in the rest of *American* manufacturing and the interaction with *German* unemployment should produce the same, positive, interaction coefficient.

But Table 12 shows that interacting the growth of manufacturing value added in a country with the *German* unemployment rate rather than the national unemployment rate does not cause the interaction terms to mimic the German pattern. The coefficient drops for England, remains negative for Norway, and for Belgium and France switches from negative to positive but remains insignificant.

These results do not suggest that the positive effect of German unemployment on the cyclical of German labor productivity is due to the correlation of German unemployment and another factor causing increased cyclical of labor productivity.³⁴

33. Finland can be included in regressions using value added per worker because average hours are not needed. The large standard error for Finland presumably reflects the difficulty of identifying national demand in a small open economy. The use of production per worker instead of production per man-hour reduces the spread of the European coefficients, making the contrast with the United States more striking.

34. The analogous question can be asked about the negative coefficients on the interaction term found for the United States: perhaps they reflect the fact that U.S. unemployment is highly correlated with lagged oil shocks. If so, regressions of other countries' productivity growth on the interaction of their growth of the rest of manufacturing and the *United States* unemployment rate should be negative.

However, when such regressions are estimated the interaction coefficient for Germany remains positive and significant (results not shown). The coefficient for England falls and is not significant, but remains positive. For other countries, coefficients remain insignificant and negative. The summary precision-weighted average coefficient on the interaction of *United States* unemployment and national rates of growth in the rest of manufacturing is positive, the opposite of what one would have expected according to the omitted variable-bias story.

NOTE: Regressions do not control for industry effects.

One final errors-in-variables problem is somewhat subtle, but easy to evaluate. The decomposition of productivity growth into trend and cycle would be difficult even if many more years of data were available. The regressions reported above do not reveal whether the interaction term reflects a change in the cyclical nature of productivity, or simply reflects changes in the trend in productivity growth which happen to be correlated with changes in the average decade-to-decade level of the unemployment rate. A confident interpretation of the coefficient on the interaction term would require many more years of data with high and with low unemployment.

It is possible with available data to control for some obvious factors which could have changed both the trend of value added and of productivity. Inclusion of a time trend had very little effect; inclusion of the capital/labor ratio had little effect also (results not shown).

It is possible to control directly for changes in the trend of productivity and value added which happen to be correlated with average unemployment rates by including unemployment itself in the regressions.³⁵ Including the unemployment rate does not affect the interaction coefficients.

35. The failure of the inclusion of the unemployment rate to materially affect the interaction coefficients should not come as a surprise. Earlier regressions did not directly control for the level of unemployment, but

As reported in Table 13, the coefficient remains significantly negative in the U.S. and positive in Germany. The difference between pooled Europe and the U.S. remains large and significant.

Assessment

None of the explorations and alternatives considered in the second half of this section shake the finding that the effect of unemployment on the cyclical nature of productivity is different in the U.S. and in Europe. In the U.S., high unemployment is correlated with low cyclical nature in productivity. This reinforces the cross-sectional evidence that labor hoarding by firms is an important component of procyclical productivity in the U.S. In Europe by contrast, the correlation between high unemployment and the cyclical nature of labor productivity is positive or statistically insignificant. This suggests that the importance of job hoarding by workers is greater in Europe. This is as one would have expected from the literature on labor market institutions.

they did remove sample means from growth rates. The effect on the interaction coefficient of the inclusion of the unemployment level is thus proportional to the covariance of output growth and the squared deviation of unemployment from its sample average, which is close to zero.

IV. CONCLUSION

This paper has reported evidence that procyclical productivity is more than the consequence of supply-side shocks propagating through a standard real business cycle model. Such theories can account for a correlation of sectoral productivity growth with aggregate value added, and can—if cost shocks affect an intermediate input, like oil, necessary for production in many sectors—account for a correlation of sectoral productivity growth with aggregate productivity.

One explanation for procyclical productivity in response to shifts in demand uncorrelated with shifts in industry supply is that a firm receives surplus from keeping a stock of workers—and that a worker receives surplus from keeping an existing job. Thus labor “hoarding” by firms and job “hoarding” by workers underlies procyclical productivity. We have not built a model of the labor market. Nevertheless, the correlations make us optimistic about the utility of such models.

The differences across countries in the elasticities of labor input with respect to value added lend some support to the view that procyclical productivity reflects the strength of attachment of workers to jobs. In the United States, the response of employment to changes in value added appears much greater than in European countries. This difference might be caused by stronger union movements and employment protection legislation in Europe making “job hoarding” a more important factor in Europe. Real business cycle theories are silent on the causes of such cross-national differences.

Moreover, the *level* of the unemployment rate appears to have an effect on the degree to which productivity is procyclical. In the United States, higher unemployment levels correspond to significantly lower procyclicality. This might be explained in a model in which firms do not have to worry about permanently losing the ability to reemploy laid-off workers when unemployment is high. In Europe, however, increased unemployment does not seem to correspond to less procyclical labor productivity. British and German labor productivity appears more, not less, procyclical under high unemployment.

This difference between the effect of unemployment on the cyclicity of productivity might be accounted for by the greater ability of European workers to resist layoffs, and their determination to do so in times of high unemployment, in a model in which labor market institutions had effects on the organization and level of real production. By contrast, it is difficult to think how to begin to construct an explanation of this cross-Atlantic pattern based on supply shocks or on increasing returns to scale. The pattern suggests that it is worth investigating whether pro-

cyclical productivity arises from institutionally influenced hiring and firing costs, and reflects the relationship between workers and firms—and not the relationship between workers and machines.
